This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the relevant national drug formulary and the drug companies' printed instructions, and their websites, before administering any of the drugs recommended in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Except as permitted under U.S. Copyright Law, no part of this book may be reprinted, reproduced, transmitted, or utilized in any form by any electronic, mechanical, or other means, now known or hereafter invented, including photocopying, microfilming, and recording, or in any information storage or retrieval system, without written permission from the publishers.

Preface

It is hard to believe that 6 years have passed since the first edition of *The Art of Aesthetic Surgery* was published. This was an immense undertaking for me, but it was also a rewarding and educational one. It was written to address the enormous demand for and interest in cosmetic surgery and the need for comprehensive information on that topic. I had not anticipated the warm reception that the book would receive from colleagues throughout the world and have been delighted, humbled, and gratified to witness its continued popularity and enthusiastic readership. Recent translations into Korean and Russian attest to the ongoing global need for education in aesthetic surgery.

Why then a second edition? Surely once was enough for a project of this magnitude. The answer is obvious: this is a dynamic field that is experiencing significant growth, with numerous exciting new developments. Interest in this topic has not abated over the years; in fact, it has grown stronger and more vibrant. While many of the procedures touted 6 years ago are still being performed, others have been replaced by new, less-invasive approaches or techniques that emphasize volume replacement to enhance rejuvenation procedures. Furthermore, new technology, noninvasive techniques, and a number of new devices, fillers, and products have enhanced our ability to provide our patients with a broader spectrum of options and improved outcomes. Clearly, there was a need for a revision of the book to reflect these dramatic and ongoing changes.

Today nonsurgical cosmetic treatments such as injectables continue to gain in popularity, while we have seen a decline in some surgical approaches to facial rejuvenation. Nowhere is this change more dramatic than in the area of brow rejuvenation. Another important trend has been the emphasis on volume enhancement in periorbital and facial rejuvenation. In keeping with these trends, we have increased coverage of nonsurgical treatments and injectables and have added new sections and chapters dealing with volume and its role in facial rejuvenation.

In contrast to the reduction in the number of invasive surgical procedures for facial rejuvenation being performed today, there has been a dramatic increase in breast and body-contouring procedures, in normal-weight patients as well as in individuals who have lost massive amounts of weight. Accompanying this burgeoning interest and demand have been advances, the development of new procedures, and refinements of existing techniques

I did not approach the task of this revision lightly. As with the first edition, it involved many late nights and weekends spent writing and editing. A busy practice, numerous academic and societal commitments, a journal editorship, and an effort to bring more balance into my own life were all forces working against such an undertaking. Then why did I feel this was the right time to take on the responsibilities and make the time commitment for editing a second edition? Obviously, there was more than one reason.

My commitment to learning and teaching was a primary motivator. From my earliest writings on muscle and musculocutaneous flaps to the editing of this three-volume work on aesthetic surgery, I have always felt an obligation to contribute to the literature and to help advance our specialty. This book represents a continuation of my lifelong dedication to this process. It has been a wonderful way to reach out to young and experienced surgeons alike and to offer them insight into the remarkable contributions made by leading experts worldwide. During academic travels and interactions with plastic surgeons and trainees all over the world, I have witnessed their interest in aesthetic surgery and their desire to master the basics of aesthetic surgery and to learn about the latest techniques. This new edition has been written to address that need and to provide information on current advances that emphasize safe and best practices to all aesthetic surgeons.

Every chapter has been revised with new material added. Thirty-nine new chapters, reflecting the growth and diversity of our specialty, have been included. The number of DVDs has also grown, with more than 20 operative videos now included in this edition. It is with great pleasure that I welcome 65 new contributors who, along with our previous contributors, bring valuable insights and considerable expertise to this new edition. These contributors have graciously succumbed to my gentle arm-twisting and have provided us with outstanding chapters on a diverse range of topics. They have all distinguished themselves as educators and innovators.

The positive feedback we have received on the clinical decision-making chapters prompted the expansion of existing chapters and the inclusion of new ones. The additions reflect the increase in the number of options now available for each patient. These chapters reflect my own daily decision-making process, not only in the operating room but also in the clinic when I evaluate new patients and care for them after the operation.

My personal interest and fascination with human anatomy dates back to my first year in medical school. I recall one of my teachers telling the class, “You will learn anatomy three times and forget it three times.” He went on to say that unlike other knowledge we would acquire over the years, anatomy would never change. Of course, he was right; anatomy does not change. However, it is important to note that we change, and our understanding of anatomy evolves and deepens with experience.

Back then, I never imagined that one day as a practicing plastic surgeon not only would I remember all the anatomy I learned, but also I would learn intricate details that were unimaginable then. Little did I know that in some modest way I would even contribute to that knowledge base. Interest in anatomic detail as it applies to aesthetic surgery continues with further clarification of facial anatomy, such as the fat compartments and more detailed descriptions of anatomy of the trunk and breast relating to emerging body-contouring procedures. In keeping with these new findings, all anatomy chapters have been appropriately updated.

The topic of patient safety also assumes a more prominent position in this edition, with a major chapter on safety considerations in aesthetic surgery as well as specific chapters on problems and complications in different anatomic regions.

The third volume, which focuses on breast surgery and body contouring, has been greatly expanded with more than 20 new chapters and many new contributing authors. We now have chapters on fat grafting to the breast, the medial and lateral pedicles in breast reduction, mastopexy and breast reduction in massive-weight-loss patients, and mastopexy-augmentation. The section on body contouring provides information on innovative liposuction techniques and on different approaches to body contouring, with new topics ranging from patient screening to brachioplasty, back and lateral fold contouring, lipoabdominoplasty, gluteal augmentation, female genital surgery, and correction of iatrogenic deformities.

We have updated all of the artwork and redesigned the look of the book to make it more modern. This includes the cover: although we have retained the theme of the “Three Graces,” which symbolizes all aspects of beauty in aesthetic surgery, our graces have now been transformed from the classic Renaissance look of the first edition to modern-day abstraction.

It is my wish that readers will receive this second edition with enthusiasm equal to that of the first publication. I hope that it will provide a source of new information, stimulate thought, and foster innovation. As with any writing project, this book has been a major undertaking, but it has also been a labor of love. I have learned as much as I have taught, and I continue to marvel at the outstanding work being done by my colleagues throughout the world. I am gratified to be able to share it with you in these pages. My goal for this book is to provide trainees as well as experienced practitioners with a solid foundation for learning basic principles and techniques in aesthetic surgery to enable them to build on this foundation and to forge new solutions to ongoing problems and challenges.

Foad Nahai

Acknowledgments

This book is intended as a testament to all of the surgical pioneers who laid the foundation for modern aesthetic surgery, as well as a tribute to current contributors whose ingenuity and skill are paving the way for future developments. While acknowledging my mentors, I also credit the young surgeons in whose training I have been privileged to participate. Their enthusiasm and quest for knowledge continues to stimulate me.

This work would never have been completed without the support and encouragement of my family, my partners, those with whom I work on a daily basis at Paces Plastic Surgery, and my friends at Quality Medical Publishing. I would be remiss if I didn't mention all of them by name. My wife, Shahnaz, has been a support and a part of my professional life for 41 years. She, more than anyone, has put up with my unusual hours and weekends away from home. My son, Farzad, in practice with me now, and daughter, Fariba, have always been interested in what I do and have encouraged me in my efforts. My partners, Rod Hester, Sonny McCord, Farzad Nahai, and Kristin Boehm, not only contributed to the book but also provided encouragement, advice, and most of all, support in looking after my patients while I was away working on the book. Linda Neal, my personal assistant and right hand for many years, and my new assistant, Lori Meeks, as well as Mary Popp, RN, and Angela Evans, RN, FA, spent endless hours gathering information and putting case histories together. Lester Robertson, who has worked with us as a physician assistant and a professional photographer for 28 years, worked tirelessly to put digital images together for all of us at Paces Plastic Surgery.

I am indebted to all at QMP, notably Brenda Bunch and Amanda Behr, whose talents as medical illustrators are only surpassed by their professionalism and their willingness to revise and rework until I was satisfied. Michelle Berger and Amy Debrecht not only encouraged but also managed to have all the contributors (and the editor as well) submit their manuscripts and videos in a somewhat timely manner. Taira Keele and Olivia Ayes provided the follow-up needed to process the chapters, check on missing items, and keep everything in order and on target. Brett Stone, with the able assistance of Thuy Khuu, did an amazing job of working with the images and the pages, providing color correction, sizing adjustments, and quality control. Suzanne Wakefield's skills as an editor not only took care of my errors but also taught me that my command of English grammar may not be all I thought it was. The intuitive,

graceful layouts and attention to detail of Susan Trail and Elaine Kitsis transformed ordinary manuscripts into a visually appealing book. Sandra Hanley scoured every corner of the pages for correctness and consistency, and Carol Hollett corrected errors and incorporated contributors' changes. With unwavering determination, Carolyn Reich shepherded the three volumes to timely publication. Andrew Berger has led the marketing and sales effort; his unique knowledge of the book's contents is invaluable in informing surgeons about its benefits and helping residents understand its value. He has ensured that this book will, along with QMP's other publications, receive unprecedented exposure through a vibrant marketing campaign and attendance at more than 30 annual plastic surgery meetings worldwide.

Most of all, I am indebted to Karen Berger, not only for her friendship of more than 30 years, but also for her encouraging me to undertake this project—and her tenacity to see it to fruition. Without exaggeration, this project may never have been completed without her assistance and hard work.

I acknowledge the outstanding contributors to the book, not only the original contributors who updated and in some cases totally rewrote their chapters, but also the new authors whose contributions have filled in any deficiencies that may have existed in the first edition. I am most grateful to them for generously and so readily sharing their expertise with us.

Contents

Volume I

Part I Fundamentals

- 1 The Patient 3
Foad Nahai
- 2 Patient Safety in Aesthetic Surgery 35
V. Leroy Young
- 3 Sedation and Anesthesia for Aesthetic Surgery 71
Donald W. Buck II, Thomas A. Mustoe
- 4 Facial Aesthetic Surgery in Skin of Color 87
Julius W. Few
 4-1 African American rhinoplasty, 104
Few
- 5 Photographic Essentials in Aesthetic Surgery 115
Farzad R. Nahai, William Y. Hoffman

Part II Business Basics

- 6 The Practice: Models, Management, and Marketing 151
Foad Nahai, Gustavo A. Colon, Wendy Lewis, Marie Czenko Kuechel, Andrew R. Berger
- 7 The Practice: Staffing, Services, and Financial Planning 193
Marie Czenko Kuechel
- 8 Aesthetic Surgery and the Law 223
Mark Gorney

Part III Nonsurgical Cosmetic Treatments

- 9 Clinical Decision-Making for Nonsurgical Cosmetic Treatments 245
Foad Nahai

- 10 Skin Care and Dermatologic Treatments** 261
Inja Bogdan Allemann, David J. Goldberg
- 11 Botulinum Toxin Injections for Facial Rejuvenation** 295
Alan Matarasso, David Shafer
-  **11-1 Botox Cosmetic and Dysport: anatomy, supplies, techniques, and results, 312**
Matarasso, Shafer
- 12 Soft Tissue Fillers in Aesthetic Facial Surgery** 329
Trevor M. Born, Lisa Airan, Dimitrios Motakis, Foad Nahai
- 13 Structural Fat Grafting: Basics and Clinical Applications in the Hand, Face, and Nose** 395
Sydney R. Coleman
- 14 Dermabrasion** 475
James L. Baker, Jr.
- 15 Chemical Peels** 493
Richard H. Bensimon, Michelle B. Locke, Foad Nahai

CHAPTER 1

Spring, Teodor Axentowicz

The Patient

FOAD NAHAI

A well-informed patient is a happy patient.

Our patients are bombarded with information about cosmetic medicine and surgery; it is a pervasive theme in our youth-oriented society, appearing in print, electronic, broadcast, and social media. Although some of the information obtained from these sources may be helpful, much of it is intended to entice rather than enlighten. Advertising for aesthetic surgery is calculated to bring patients into the surgeon's office, often by promising more than can be delivered while minimizing risks, complications, and the possibility of unfavorable or suboptimal results. Websites and social media devoted to cosmetic medicine and aesthetic surgery often overload patients with information promoting one procedure over another. Although the information in itself is not detrimental, it can be confusing. Patients may not have the medical background, experience, or sophistication to sort through this material to make an informed decision. The more conflicting information they receive, the more confusing it becomes, and often the more unrealistic their expectations. It is the surgeon's responsibility to educate the patient by presenting the facts in an unbiased manner. Even then, patients may not be able to reach a decision and may rely on the surgeon's recommendations, trusting his or her knowledge and abilities.

It is this basic concept of trust that is being eroded through the blatant marketing of aesthetic procedures and materials to the public. The implication from this promotional activity is that aesthetic surgeons are mere vendors of a commodity. Having a breast augmentation is not like buying a bra or lingerie, and a face lift is not like purchasing a high-end luxury automobile, where one shops for the most convenient dealership or the best discounts. Nothing could be further from the truth. We are not selling a product; we are providing a service—a service that is personal and customized to each patient, one that carries risks unlike those encountered at the beauty salon or spa. This is a high-end service that encompasses the entire patient experience. This experience begins with the initial telephone inquiry. It progresses through encounters with the receptionist, patient coordinator, nurse, and surgeon, culminating in the surgical procedure. The success of this experience is strongly dependent on the surgeon's skill, experience, and judgment.

Not all surgeons have the same experience, medical knowledge, training, surgical expertise, or technical ability. The well-informed patient should choose a surgeon based on trust, not on hype or cost.

The First Consultation

The decision to seek cosmetic treatments or aesthetic surgery is usually not a spontaneous one. Most likely the patient has been contemplating this possibility for months, if not years, before picking up the phone to make an appointment with a plastic surgeon. Some patients may have extensively researched the procedure, the surgeon, and the surgeon's practice through the Internet and in particular the surgeon's website. Others rely solely on the recommendations of friends and family. These recommendations are best when they are based on personal experience. Satisfied patients are the ideal source of referrals, and far more valuable than any advertising, promotions, or even marketing that money could buy.

The initial consultation does not necessarily begin with the first phone call to schedule an appointment. Most likely the prospective patient has already visited the practice's website, and the first contact may have been through the website. The website and the first telephone contact leave a lasting impression with the patient; if those contacts are unfavorable, the patient may decide against making an appointment or fail to keep it. Prompt responses to the patient's inquiry through the website and proper telephone etiquette are of utmost importance. The phone should be answered after a maximum of five rings, and the voice that greets the caller should be cheerful and inviting, announcing the name of the practice and the name of the person answering, followed by, "How may I help you?" This greeting should be spoken in a clear, understandable voice. Such an encounter will leave the caller with a positive impression. Conversely, an unfavorable impression may be left when the phone is answered by a programmed voice reeling off a list of options, each requiring a separate button to be pushed, until the irritated caller is either disconnected or put in touch with the appropriate person. This type of impersonal answering system can alienate potential patients. By the time the annoyed caller actually reaches a live person, he or she is not in any mood to discuss aesthetic surgery. In any high-end service, immediate contact with a caring individual is essential.

In most offices, the caller is first connected with the person responsible for scheduling appointments. This person needs to understand the importance of flexibility, even for surgeons who are fortunate enough to have large practices with few immediate openings for new patients. Impressive as it may sound to inform a patient that there are no openings because the surgeon is fully booked for 18 months or longer, in most cases rather than impressing the patient, this will only encourage him or her to look elsewhere. We live in a world where everyone is busy. Most of our patients value their time as we do and only have specific days and times when they can afford to miss work for a doctor's appointment. This is particularly true for those seeking aesthetic surgery, who do not wish to ask for sick time or announce to their supervisor that they are going to see a plastic surgeon.

Your website is the face of your practice to the world.

Although we may not always be able to accommodate every patient's scheduling needs for every office visit, it is important to do so for the initial consultation. For this reason, some practices offer evening and Saturday office hours. Patients should be asked how soon they would like to schedule the appointment. Then every effort should be made to schedule the appointment as close to that date as possible, without overcommitting the surgeon, yet leaving sufficient time for the initial consultation. (In my practice, at least 1 hour is allotted.) Although patients assume that doctors are never on time, patients still make every effort to arrive as scheduled. It is a matter of common courtesy, whenever feasible, to see patients at the appointed time. Obviously, this is not always possible. It is good practice, however, to notify patients if you are running late either before they arrive, if possible, or on their arrival.

The scheduler should record the caller's name, address, and contact information. It is also important to inquire about the reason for the consultation. Some individuals may be reluctant to disclose this information to a stranger on the phone. The scheduler should explain that while patient privacy is of the utmost importance, these questions are being posed to determine whether the practice offers the procedure that the patient is seeking. It also provides valuable information for the surgeon to help prepare for the patient's initial consultation and to ensure that sufficient time is allotted for that appointment. Patients seeking removal of a skin lesion may not require as much time at the initial visit as someone seeking facial rejuvenation. Once the appointment is made, patients are told that a package will be mailed to them or can be downloaded from the website. Most practices now offer patients the option of filling out their initial paperwork online, thus eliminating the need to do so in the doctor's waiting room during the initial visit.

Some patients may not want to receive mail, phone calls, faxes, emails, or other communications that are identified as coming from a plastic surgeon's office. Special care should be taken to cater to these needs. The scheduler should ask where the patient would like to receive correspondence from the office. Some thought should be given to using envelopes and fax cover sheets without any indication that this is coming from a plastic surgeon's office; envelopes should have a street address without a practice name or logo. In the interest of patient confidentiality, the scheduler should also specifically ask patients how they wish to be contacted by the practice, for example, home, cell, or office phone, or by email.

Next, an information package is sent from the office that includes general information about the practice, maps and directions, specific information about the surgeon, his or her qualifications and practice philosophy, a letter detailing what will happen during the initial consultation, and a brochure on the procedure the patient is seeking. Most, if not all, of this information is probably already available on the surgeon's practice website. However, it is important to remember that not all patients are Internet savvy, and some may prefer a hard copy; therefore the printed material serves as a reliable resource for all patients regardless of their technical know-how.

Maps and directions to the surgeon's office should be sufficiently detailed to allow patients to easily locate the office. Parking should be ample and convenient. Any special parking instructions should be detailed in the information package. Even though a patient is looking forward to the visit with the plastic surgeon, this initial consultation is a stressful event; getting lost or frustrated over finding a parking space will merely add to patient anxiety.

On the next page is an example of the type of patient letter that is sent with our practice information package.

The patient's first face-to-face encounter in the surgeon's office will be with the receptionist, who should greet the patient and notify the patient coordinator or nurse of the patient's arrival. It is disconcerting for a patient to walk into the surgeon's office for the first time, only to find that no one is there to greet her or him; even worse is when two or three staff members are engrossed in conversation or occupied on the telephone, and the patient is ignored. It is also essential that we respect the patient's privacy during this sign-in process; several points merit particular attention.

Privacy and HIPAA Regulations

Sign-in lists where the patient signs his or her name under the name of the previous patient should be avoided.

The receptionist should sit in an enclosed space, preferably in a glass-enclosed area to maintain privacy yet allow the receptionist to have full view of the waiting room. The receptionist or nurse should refrain from loudly announcing the patient's name in the waiting room.

Under no circumstances should the patient be greeted with the words, "You are here to see Dr. Nahai about your breast enlargement?"

In most states in the United States and in some other countries, the practice is required to display a Patient's Bill of Rights and the privacy statement.

Once a patient has signed in, he or she should be told when to expect to be taken to the consultation room to meet with the patient coordinator. If there is a delay, the patient is given an estimate of the waiting time, and coffee or a soft drink can be offered. Whenever possible, an explanation is provided for the delay. If the delay is inordinate or unacceptable, the patient is offered the choice of rescheduling or waiting. If I am running unacceptably late—a half hour or more—the fee for the initial consultation will be waived and the patient's parking charges paid as a gesture of goodwill.

The patient is then escorted to one of the examination rooms. In my practice, the nurse meets with the patient first. A history is taken and the completed health questionnaire, which has been downloaded from the website or mailed out to the patient before the initial office visit, is reviewed.

Text continued on p. 15

Dear Patient:

I am looking forward to meeting you when you come in for your initial consultation with Dr. _____.
A map and directions to our location are enclosed for your convenience. Parking is available, as indicated on the map.

We are located in the _____ building on the _____ floor. Elevators are located in the lobby of the main entrance to our building and on level _____ of the parking deck.

We realize your time is valuable; please allow 1½ to 2 hours for your consultation. This will permit ample time for your consultation with Dr. _____, for photography and video imaging, and for consultation with our aesthetician, as appropriate. I will also meet with you to discuss the surgical fees and scheduling, and to answer any questions you might have. Most of all, you will be able to familiarize yourself with our practice, our facility, and the staff, without time constraints.

We look forward to seeing you soon. In the meantime, if you have any questions or if you need further information, please feel free to contact me at any time.

Sincerely,

Patient Coordinator

At this time the patient usually discusses the reason for the consultation with the nurse. This takes from 10 to 20 minutes, depending on the patient, the nurse, and the procedure. I then review this information before meeting with the patient. I greet the patient and introduce myself and immediately ask, “What can I do for you?” We then discuss the patient’s goals and what he or she hopes to accomplish through aesthetic surgery. Next we review the patient’s history, including pertinent information on general health and specific information concerning previous aesthetic treatments, procedures, and skin care. Procedure-specific information is discussed in detail. For example, any woman desiring breast surgery is asked specifically about her family history of breast disease, including cancer, history of breast masses and biopsies, mammography, and childbearing history. If the patient is contemplating liposuction or body-contouring procedures, we discuss lifestyle, exercise, nutrition, and weight control. For abdominal procedures, we discuss previous abdominal operations, including liposuction and hernia surgery. For facial rejuvenation procedures, I ask whether patients are currently smoking, but I am also interested in their smoking history—that is, if they have ever smoked, for how long, how heavily, and when did they stop? I question all patients about a history of phlebitis or deep venous thrombosis.

Once the history has been reviewed, I return to the reason for the consultation. Throughout this consultation, I know that the patient is assessing me as a person, a physician, and a surgeon. Clearly, he or she has no way of realistically evaluating my knowledge of aesthetic surgery or my technical abilities. In all likelihood, patients will base their decisions on my demeanor and how warm, caring, and attentive I appear. Meanwhile, I am assessing the patient. Are his or her goals realistic? Will I be able to meet these goals? Do I like the individual? If we have a complication, will I be able to maintain patient confidence while we resolve the problem? I am particularly attentive to the patient’s body language, eye contact, tone of voice, and most of all, his or her enthusiasm and interest during the consultation. I observe the patient’s appearance, hairstyle, makeup, clothing, and accessories. These not only reflect the patient’s tastes but also attention to detail and how exacting the individual will be as a patient. I am concerned when an individual who is sloppily dressed and poorly groomed comes in seeking aesthetic surgery. In a similar manner, the appearance and grooming of the surgeon leaves an important impression about the surgeon’s attention to detail and the care, attention, and meticulous surgical technique that he or she offers to each patient. I certainly would be hesitant to let any sloppily dressed or poorly groomed physician or nurse take care of me!

It is not unusual for patients to come in having researched the procedure on the Internet or on other physicians’ websites. In all likelihood they have sought consultation elsewhere as well. They may have been given conflicting advice and information, which they may or may not share with me. Close to the end of our consultation, I now ask them if I have told them anything that they were not aware of or anything that conflicts with information they may have been given elsewhere.

Dear Patient:

It was nice to meet you at _____ Plastic Surgery on _____. As we discussed, you are a good candidate for breast enlargement. With this operation, we plan to place a saline implant (filled with saltwater) under the muscle of your chest through an incision in the crease below each of your breasts. I am aware of your desires for final breast size and will do my best to address them. However, please remember that we will select your implants based on the dimensions of your breasts rather than the volume of the implants. The operation will be performed in our operating rooms as an outpatient procedure.

It is important to understand that breast augmentation is not maintenance free; the implants are not permanent, will eventually fail, and have to be changed. There is always the risk of capsular contraction (hardening of the breast), which may also necessitate reoperation and implant change. I would be happy to meet with you again to go over this and the other risks and complications that we have discussed before you make a final decision. In the meantime, if you need any more information or if we can assist you in any way, please don't hesitate to call.

Best wishes.

Sincerely,

_____, MD
(Physician Name)

Most patients respond that they were aware of some but not all of the information that we provided. In my experience, this new information is almost always related to expected outcomes and complications. It amazes me that even today I see patients who have researched breast augmentation on the Internet and have had consultations elsewhere, but may not be aware that breast implants are not permanent.

I never pressure patients to make a decision during the initial visit. In fact, I encourage them to ask questions, take home the materials we provide, and to return for a second visit, which is complimentary, before making a final decision. However, we do arrange for our patient coordinator to quote fees and discuss scheduling during this first visit.

I follow up every new consultation with a personal letter rather than a form letter, summarizing our discussion and a brief description of my recommendations; I remind patients that I would be happy to meet with them again before they make a decision or schedule a procedure.

Motivation

A well-motivated patient is a happy patient.

Understanding patient motivation is an essential goal of the initial consultation. Questions probe the reasons for seeking surgery. For whom is the patient pursuing the operation—is it to please someone else? Does the patient think that this will change his or her life? The best patients are those who are seeking surgery for themselves so they can look better. The best motivation is self-improvement. With most patients, I am able to understand what motivates them after a few minutes. Sometimes I will ask patients whether they hope that the aesthetic surgery will change anything in their lives and inquire as to whose idea it was for them to have this procedure.

Almost always, teenagers seeking rhinoplasty or other aesthetic procedures suitable for their age are accompanied by a parent. I make it a point to address the teenagers directly and have them, rather than the parent, tell me what they would like. I usually tell them that they will have to live with the result, not their parents or their surgeon, so they need to carefully consider what they are requesting. Although I will allow the parents to express their opinions, I make it clear to the patients that they should make the final decision.

Patients often have hidden agendas—secret and personal reasons for seeking this procedure. They are reluctant to share this with the surgeon or the staff, and even with their family and friends. These hidden agendas may include attracting the opposite sex, seeking a promotion, or simply a life-altering event. Beware of this hidden

agenda, because despite an excellent result, these patients will never be happy unless the requirements of the hidden agenda have been fulfilled.

When to Say No

Not every person I see is a candidate for a surgical procedure. I classify noncandidates into six general categories, as follows:

1. *Those seeking the procedure before they are ready for it*
For example, breast augmentation for teenagers, face lifts in women who do not need one or who will see little difference, or rhinoplasty in 12-year-olds
2. *Those with unrealistic expectations*
For example, those patients who believe that aesthetic surgery will “change their lives,” save a marriage, or make them look like swimsuit models or movie stars
3. *Patients on whom I would prefer not to operate*
For example, those who are overly demanding, noncompliant, abusive to office staff, or “aesthetic surgery junkies”
4. *Another surgeon’s unhappy patient who has a reasonable result but remains extremely critical of the original surgeon*
5. *Patients who are psychologically unstable*
6. *Those who are seeking to improve on problem areas or imperfections that are not readily recognized by others; these individuals may well have body dysmorphic disorder (BDD)*

Patients in group 1 are counseled that it is too early for the procedure they are seeking. I explain to these patients that I would like them to be my patients and that I will operate on them at the appropriate time. A woman seeking a face lift before she is truly ready will be offered skin care, other ancillary procedures, and injectables, if appropriate, until they are ready for a surgical procedure. I explain to teenagers seeking augmentation that it is best to wait until their breasts have stopped growing. I will make an exception for teenagers with significant breast asymmetry and promise the 12-year-old that as soon as her nose is fully grown, we will take care of it.

I explain to patients in group 2 that I do not believe I can provide them with the result they are looking for or meet their expectations. I also let them know that I am concerned that they will be unhappy or displeased with me.

Patients in group 3 require special tact. I tell these demanding patients that I do not believe that our office will be able to provide them with the level of service that they are seeking. To the abusive patient I explain that the office staff and I are a team and because the patient has already indicated an unwillingness to work with my office staff, I cannot care for this individual because I will not work without my colleagues. Finally, to the patient who has an insatiable desire for plastic surgery, I say you have had it all and it is too early to have any more.

Dissatisfied or unhappy patients in group 4 are told that they have had a reasonable result, that they are being unduly tough on their previous surgeon, and that I doubt I can significantly improve on what has been done. My major concern is that a patient with an average result who is trashing the original surgeon will one day say the same about me, regardless of the result. Any patient who walks in and unjustifiably claims that they were “butchered” or “mutilated” is an immediate noncandidate.

Group 5 includes psychologically unstable patients whose instability is not always readily discernible. I advise them to seek counseling and treatment before considering aesthetic surgery. In fact, anyone under psychiatric care at the time of consultation, regardless of my own personal impression of his or her suitability, is referred back to the psychologist or psychiatrist for clearance before scheduling. It is not uncommon today to see patients who are taking antidepressants such as fluoxetine (Prozac) or bupropion (Wellbutrin). This by itself does not disqualify them, as long as they are stable individuals. Most of the time the antidepressants have been prescribed by their internist or family physician for mild depression rather than for any severe psychiatric condition. Most of these individuals are suitable candidates for aesthetic surgery.

Group 6 individuals may appear normal to the untrained; however, their insistence that a small blemish or minimal deviation from the norm is a major deformity that is ruining their lives and incapacitating them is an indication of BDD. These individuals should be referred for counseling. Surgical or other procedures on these patients lead to further dissatisfaction, disappointment, and anger. Extreme caution should be exercised in handling this group.

I discuss the options available to the patient and make my recommendations. I explain that I prefer to operate in our own office-based surgical center, which is certified and inspected by the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF) and the state of Georgia. I tell patients that anesthesia will be provided under the supervision of a board-certified anesthesiologist and that I personally will perform the entire operation. I explain that they will be charged for the consultation that day, and if I operate on them, they will be expected to prepay for the surgery. All follow-up visits before and after the operation are included in the charges for the surgery. I do not discuss specific fees and charges; our patient coordinator does that. I do, however, explain to patients that I will perform revisions, if needed, at no additional charge. Although rare, should a complication necessitate the services of other physicians or hospitalization, those expenses would be the patient's responsibility. Years ago, Dr. Gil Gradinger shared with me a letter that he gave to his patients on this subject. I still use a modified version (p. 20) that patients are asked to read and sign before surgery.

However, my no-charge policy for revisions does not always apply to liposuction patients, who often return seeking revisions and repeat liposuction after weight gain,

To My Patients:

Prior to surgery, you will have paid my fee as well as other costs. Although it is very unusual, complications requiring additional surgery, consultation, hospitalization, or other services can occur. There will be no additional charges for any service performed by me or the staff. However, any other doctor, hospital, or related expenses will be your responsibility.

Healing after an operation is usually a predictable process leading to a good result. However, occasionally a surgical revision is necessary to help achieve this result. In this situation there will be no charge for my services, but there may be a small facility charge.

_____, MD

I understand and accept the above statements.

(Patient Signature)

(Date)

To My Liposuction Patients:

Approximately two to three weeks after the operation, you will notice some decrease in your weight. The actual weight loss will of course depend on the volume of fat that was removed. Following the operation, it is important that you maintain your weight and avoid any weight gain. Maintaining your weight, or better still, losing weight postoperatively will only enhance your result. In contrast, any weight gain will have the opposite effect.

Normally, there is no charge for a revision or touch-up of liposuction if done within one year of the original surgery, provided your weight has remained the same. However, if there has been a weight gain of 10 pounds or more postoperatively, there will be a fee for any revision.

In order to maintain your good result following liposuction, I encourage you to maintain your weight!

thereby obviating the results of the original procedure. To avoid future misunderstandings, we talk to these patients preoperatively about the impact of weight gain on long-term liposuction results. Liposuction patients are asked to read and sign an additional form regarding weight gain and repeat procedures (p. 21) so that they fully understand that additional liposuction after a substantial weight gain (10 pounds or more) will not be considered a revision but a new procedure.

Surgeon Shopping

Currently the public is being advised to seek two if not more consultations before selecting a plastic surgeon, so most patients will see another surgeon before proceeding. Although a second or third opinion is not unusual today, I would be wary of patients who have seen numerous plastic surgeons. Occasionally a patient comes in with an information package and video images from another practice and a file full of information and images downloaded from the Internet. Sometimes the patient tells me that a different procedure was recommended by others. This in itself is not a red flag to me, but it requires extra time and discussion. I explain that each surgeon will recommend an operation that, in his or her hands, comes as close as possible to the patient's desired goal. I assure the patient that I have done the same. The fact that my recommendation differs from that of the other surgeon (or surgeons) does not necessarily mean that I am correct and the other surgeons are not; it simply means that I have recommended a procedure that, in my hands, would give the patient the best result.

I tell patients who have seen other surgeons that they should not base their choice of physician on price, on who has the fanciest or sparsest office, or on convenience of location. Rather, the choice should be based on the overall impression of the physician and the office staff, rapport with them, and most of all, confidence and trust. I explain to patients that even in the best of hands complications are possible, and that they should have enough confidence and trust in the surgeon they choose to allow him or her to handle any problems through to resolution. Patients often make the mistake of going to another physician once they have developed a complication, even though the original surgeon would be equally capable of dealing with it. These patients often blame themselves and are convinced that they made the wrong choice. I tell them that if they choose me, they should have enough confidence to allow me to handle any complication unless I recommend that they see someone else.

Patient Education

I discuss outcomes, risks, and complications with the patient during the initial consultation. All patients are informed that all procedures carry risks and that cosmetic treatments and aesthetic surgery are no exception. I explain that the risk of a life-threatening complication is not as small as the risk of flying—and significantly less than driving around Atlanta. Once the patient is reassured in terms of general risks,

I address specific risks. All of my patients are told that infection and bleeding are common to all aesthetic procedures but are extremely rare. I do prepare them for postoperative bruising and swelling which may accompany all cosmetic procedures and aesthetic operations. I explain to all face-lift patients that in my hands the most common complication is hematoma, and the risk is currently 1%; the risk is higher in men, in persons with uncontrolled high blood pressure, and in anyone who is troubled by postoperative nausea and vomiting. I tell them that every precaution will be taken to minimize the risk, but it cannot be eliminated entirely. I add that the risk of permanent nerve damage is extremely rare—on the order of 1 in 1000 cases or less. I inform them that all surgical procedures leave scars and that the quality of the scar reflects not only the surgeon's skill (most patients believe that scars are related solely to the surgeon's skill and that plastic surgery leaves no scars), but also the patient's body chemistry, location of the scar, and tension. I stress that we can improve on any obvious, unsightly, or unacceptable scar through conservative means and, if needed, a scar revision can be done at no additional charge.

I also explain to my patients that although serious complications are rare, reoperations are more common. I will reoperate on a patient whose result falls short of my own expectations as well as those of the patient. These revisions are at no cost to the patient. However, if I feel that the result is the best I can achieve and the patient is still dissatisfied, then I recommend a second opinion. In addition to my explanations, the patient coordinator also reviews the more common complications associated with each procedure, such as capsular contracture, implant failure, and nipple-areolar sensory changes following breast augmentation. Eventually patients also receive a letter and informed consent form, which they are asked to read, initial each page, and sign on the last page. These documents enumerate the complications.

We also discuss postoperative management, including an overnight stay in our suites if needed, the frequency of postoperative visits, restriction of work and other activities, and the expected time to full recovery. I do not minimize the length of time needed for complete resolution of all bruising and swelling. I tell all face lift and blepharoplasty patients that it may take up to 5 weeks for them to look “normal” without makeup.

My first encounter with the patient lasts from 15 to 30 minutes. After that the patient is sent to the photography room, where our professional photographer will do the video imaging. I have found video imaging to be very helpful with facial aesthetic procedures and rhinoplasty. Video imaging is not routinely offered to our breast or body-contouring patients, although there is now some new software that may well make video imaging for body contouring as reliable as it has been for the face and nose. Three-dimensional imaging, though currently very expensive, may one day contribute further not only to video imaging but also to preoperative and postoperative evaluation of results.

All patients are given the opportunity to review our preoperative and postoperative album. Most will have already seen similar images on our website. It is not unusual for patients to even base their decision to come in for a consultation on the before and after images that are posted on the website. Without exception, we show preoperative and postoperative reduction and mastopexy images so the patient will have a clear understanding of the location of the scars. After the video imaging session, I review the projected result and discuss with the patient whether that result is realistic and how close we can approximate it. No promise or implied guarantee of a result is made. At this time the preoperative and postoperative album is reviewed with the patient if needed. Usually it is the patient coordinator and the photographer who show the album to the patient. We do encourage our patients to bring in photographs to demonstrate what they like. For example, rhinoplasty patients bring in pictures of noses that they like and those they do not; the same is true for breast augmentation patients. Reviewing these pictures with the patient provides me with further insight into the patient's aesthetic goals. For facial rejuvenation patients, we ask that they bring in photographs taken 5, 10, and even 15 or 20 years earlier so that we can better assess their features.

At the end of the consultation, the patient spends additional time with the patient coordinator, who will discuss fees, scheduling, and the preoperative routine to be expected. The coordinator again describes the procedure, risks, likely outcomes, and expected recovery. If an overnight stay is planned, an album containing images of our overnight suites is shown to the patient. Occasionally the patient will ask to see the operating rooms and overnight suites. If there is an unoccupied overnight suite and the recovery room is empty, we will accommodate this request. A video tour of our facilities is also available on our website. Most patients will, in fact, schedule or at least ask to have time reserved at that initial visit. We do encourage them to think about things and offer them a return visit before they schedule or the option to schedule by telephone.

Financial Responsibilities

Although the major source of patient dissatisfaction is a result that does not meet expectations, financial misunderstandings and problems with fees are also common sources of patient anger. Far too many patients who were initially happy with their excellent results become dissatisfied and find fault with their results if unexpected charges appear long after the operation has been completed. Financial surprises should be avoided if at all possible.

My patient coordinator clearly delineates the patient's financial responsibilities during the initial visit. The patient is given an itemized quote that includes the surgeon's fee, facilities fee (including anesthesia), charges for an overnight stay, and any im-

plantable devices. It is also made clear that if other procedures are added between the time the patient has prepaid for the procedure and the actual operation, there will be additional fees. The coordinator also explains that if any specimens are removed (such as moles, breast tissues, or breast implants) and sent to the pathologist, there will be a separate bill from the pathologist. We cannot give them a quotation for the pathologist's services; this must come from the pathology laboratory.

In our own surgicenter we do not charge the patient extra if a planned procedure takes longer than anticipated. However, this may not be the case if the procedure is scheduled elsewhere. Far too many patients have prepaid for a 4-hour procedure in a hospital-based surgicenter only to later be billed for extra time when the procedure runs long. Under these circumstances it should be made clear to the patient that although the surgeon's fee is prepaid in full, the surgicenter facility fees are only an estimate, and the actual amount will vary according to the length of time, materials, and equipment used in the surgicenter. The patient may, in fact, receive a bill for the balance several days, weeks, or even months after the procedure. If this policy has been clearly explained, patients are less likely to be dismayed and upset.

Another cause of confusion about financial responsibilities concerns cases in which a combination of aesthetic and reconstructive procedures is performed (for example, nasal airway surgery and cosmetic rhinoplasty or second-stage breast reconstruction combined with aesthetic facial surgery or body contouring), where a third party is responsible for the reconstructive portion and the patient for the aesthetic portion. It may sometimes be difficult, if not totally impossible, to exactly delineate the patient's financial responsibility for these procedures. We have a person in our practice who meets with patients to discuss insurance coverage and such financial problems. Despite all of these efforts, patients must understand that the total cost of all of these combined procedures and their specific financial responsibility may not be determined until long after the procedure. If patients are prepared for a possible financial surprise, they are less likely to become angry and find fault with the result. The patient coordinator and I also discuss financial responsibilities in case of complications, hospitalization, or consultation with other physicians.

Operating on Colleagues, Friends, and Family

As a practice is built and a reputation is gained, colleagues, coworkers, friends, and family will seek your services. This is a tremendous compliment to you as a physician and to your skills as a surgeon. Although this is flattering, the surgeon should understand that it can also be a significant financial drain, because this group of patients expects discounted or even complimentary surgery. Not only do such discounts and complimentary procedures generate little or no revenue to help meet overhead and malpractice costs, but also the time spent on such discounted procedures could

To My Dear Friends and Family:

During the many years that I have been in the practice of plastic surgery, I have extended full courtesy fees to close friends and doctors as a matter of principle. Over the years, I have been fortunate to gain more friends and to enjoy the professional confidence of doctors' families, to the extent that a significant part of my time is now consumed in performing such surgery.

Sadly, with the increasing costs of overhead in the practice of surgery today, not to mention the excessive and growing premium for malpractice insurance, it is no longer possible for me to fully extend such courtesies. Needless to say, it is embarrassing and distasteful for me to charge my usual fees to close friends and colleagues. Therefore, I am pleased to be able to extend a modest courtesy discount. Since all I have to offer is the expertise and skill I have developed as well as my time, I hope you will understand.

Sincerely,

_____, MD
(Physician Name)

have been spent on patients who produce full revenue. Despite this, most surgeons have a sense of obligation to discount services for this group or to selectively provide them on a complimentary basis. Your practice should have a clear policy for such discounts and free services.

I routinely discount my surgical fee for fellow physicians and their families, nurses, and other health care professionals. The amount of the discount will vary, depending on the closeness of my professional relationship with the individual in question. The same is true in dealing with friends and family. Some colleagues and family come in for a consultation expecting to pay full fees, yet others come in expecting free surgery. It is somewhat embarrassing, if not difficult, to discuss this face-to-face with colleagues, friends, and family. Years ago, Dr. Tom Rees shared with me a note that he had colleagues, friends, and family read explaining his policy for extending professional courtesy. I found the letter most useful, and to this day I use the modified version shown on p. 26.

For our office staff, the procedures are usually provided free of charge on an individual basis, reflecting the person's length of service. Each practice should have a clearly delineated policy on employee discounts. It is wise to avoid providing discounted or free operations to patients who hold out the promise of future referrals. These usually do not materialize once the operation has been completed and may well raise ethical issues.

Patient Documentation

I make every effort to dictate the office notes as soon as I have concluded the initial consultation. Although I take additional notes while I am talking to the patient, I make every effort to maintain eye contact with my patient rather than spend the entire time scribbling notes or being preoccupied with the chart. If at all possible, I limit interruptions to those that are absolutely necessary, such as emergencies. I put my cell phone on vibrate mode and ask all our nurses to do the same. It is not conducive to a thorough initial evaluation to have constant interruptions, and I will not leave a patient while I answer a phone call unless it truly is an emergency. It is important to sit down with the patient and focus your attention on him or her. You want to leave the impression that you have plenty of time to talk. Therefore I do not look at my watch or time myself when I am with a patient. I like to have a nurse or assistant present in the room at all times, and I feel it is mandatory to have a female nurse or assistant with me when I examine a female patient for breast augmentation or body contouring, not only to put the patient at ease but also for my own protection.

Once the procedure is scheduled, the patient is given instructions in preparation for the operation. These include prescriptions for skin preparation before chemical peels and laser resurfacing and lists of medications and supplements to avoid taking preoperatively to minimize postoperative bleeding and bruising. We encourage patients to take vitamin C. Patients are scheduled for a preoperative visit 1 or 2 weeks before the operation. Patients who will undergo general anesthesia need to have a physical examination, blood test, and clearance from their primary physician before surgery is scheduled. During the preoperative visit, the patient will meet the anesthesiologist, who performs another preoperative evaluation. The patient also meets again with the coordinator to review and sign the informed consent form and to have any further questions answered. If preoperative photographs have not already been taken, they are taken on this occasion. During this preoperative visit, the patient talks with our financial counselor, who goes over the fees and collects prepayment for the full amount of the procedure, including the surgeon's fee, facility fee, and fees for the overnight stay and materials. If there is any question that additional payments may be necessary after the operation, such as a pathologist's bill, this is clearly pointed out to the patient.

The patient will be evaluating the level of service before the procedure, because it serves as an indication of how well the practice will respond to her or his needs and concerns after the operation. If the patient feels that the staff were not attentive enough, slow to respond, and evasive before the operation, he or she will be concerned this may well be what they should expect after the operation. Unfavorable preoperative experience may justifiably lead the patient to cancel the procedure.

On the day of the operation, I review the patient's record before I meet with the patient to discuss the planned procedures. I take my own finger or a cotton swab and go over every proposed incision. I then mark the patient. If he or she is accompanied by a family member and allows that person to remain in the room, I ask the patient and the family member if they have any questions and inquire whether the patient remembers the risks, possible complications, and length of recovery. It's not unusual for patients at the last minute in the preoperative area to ask whether we could take off skin lesions, add an extra area for liposuction, or even add a completely new procedure. For that reason, and to avoid any postoperative misunderstandings, I confirm with the patient that we have neither left out any procedures nor added anything. I explain that if the patient wishes to add extra procedures and operative time is available, there will be an extra charge, and the patient will be billed for it. If he or she requests excision of a skin lesion or two or a small additional area for liposuction or fat injection, I often as a courtesy include that without extra charge. However, I mention that the pathologist will send a bill for examining the excised lesions.

We then proceed to the operating room. There is a special waiting area for family members if they choose to wait; if not, I ask for a phone number so that I can personally call when the operation is finished and the patient is in the recovery room.

I also inform the patient and the family that if the operation is completed in less time than I had allotted, it does not mean that I rushed through it, and conversely, if it takes longer, it does not mean that either the patient or I encountered a problem.

After the operation, patients either go home with a responsible adult or stay in our recovery suites. If the patient goes home, I call that evening to inquire whether the patient is comfortable and whether there are any questions. If I am greeted by the answering machine, I leave a message that I called to make sure that the patient is home and comfortable. I ask the patient to call if there are questions or problems. If the patient remains in our suites, either I visit or someone on the team visits the patient. Two days postoperatively, all patients receive a follow-up phone call from our surgicenter asking them how they are doing and inquiring about their experience with the center.

Postoperative Visits

Follow-up visits are as important as the initial consultation. Most patients are concerned that the red carpet and VIP treatment will be rolled out preoperatively so that they will sign up for an operation, and that their postoperative care will be less attentive, relegated to the nurses. It is important for them to have a favorable experience in their postoperative visits. We make every effort to usher postoperative facial patients straight into a private waiting room or examination room to minimize their time in our public places, such as the general waiting room. I go in and sit and greet the patient, ask how he or she has been, and how the recovery is progressing. I explain that the nurses will clean the wounds, remove sutures, and change tapes, and that our aesthetician will take care of the areas that may have been resurfaced. I inquire whether the patient needs more medication and explain that I will return for a more thorough examination once the nurses have removed sutures and cleaned the wounds. As with preoperative examinations, a nurse is present during the postoperative examination of a breast augmentation or body-contouring patient, to put the patient at ease and for my protection. It is important to close the door, sit down, make eye contact, and talk to the patient. I do not flip through the chart, read through it, or write in it. Leaving the door open, standing, reading, and writing in the chart leaves the patient with the impression that you breezed in for a few seconds, wrote in the chart, and left without examining him or her. When I return to see the patient, I examine every suture line and express my own opinion about the early results and stage of recovery. I then answer questions. If the patient is at the stage in a facial procedure where camouflage makeup can be applied, our aesthetician applies makeup, and I see the patient after this application. For patients who have undergone breast augmentation or body-contouring procedures and have recovered sufficiently, I go back in and see them when they are fully dressed to make certain they are happy with their appearance in their clothes.

Occasionally, despite my best efforts, a patient complains to the nurse that I have not been attentive enough or spent enough time after the operation. This is an important line of communication between the patient and me, and I listen to the nurse and make every effort to resolve the situation. Very often a patient who is concerned about the result may discuss it first with the nurse or patient coordinator for fear of offending the surgeon: “I don’t want to hurt his feelings.” These communications are important and are dealt with in a kind and understanding fashion. I explain to my patients that I want them to be comfortable and open with me and discuss their concerns. My feelings will not be hurt if I am told that a patient is less than satisfied with the result. I tell patients that my feelings would be hurt if they felt that they couldn’t communicate with me and chose to go elsewhere.

I rely heavily on the impressions of our nurse and patient coordinator. It is crucially important to surround yourself with good people and to listen to them. I have turned down patients based on recommendations from these professionals and have been able to diffuse potentially unpleasant situations based on their input.

Management of Complications and Problems

No one wants complications. I take all complications personally and replay the entire procedure in my mind, wondering how and why they occurred. Despite my explanations to my patients that complications do occur, even in the best of hands, it is difficult for me to accept that my patient has developed a complication. Regardless of these personal feelings and the sense of disappointment, it is necessary to deal with these problems, and more important with the patient’s anxieties, concerns, and possible resentment. Most patients feel that something went wrong, something was not done properly—otherwise they would have sailed through the operation as smoothly as their friend did, on whom your partner, your colleague, or even you operated. I usually explain the nature of the complication to the patient. If I have any idea why it happened, I explain that and outline our plan to take care of it. I usually tell the patient, “I am sorry this happened; it isn’t anything you did; it isn’t anything I did. Despite our best efforts, we have a problem. It is not the first time I have seen it, and we know how to take care of it.” I then explain exactly what has to be done and how long it will take.

In cases of postoperative hematoma in a face lift, I reoperate usually with the patient under local anesthesia, but I use general anesthesia if needed, and I explain to the patient that this will take care of the problem. It will not affect the results, but it will leave more bruising than expected, and the affected side of the face (if unilateral) will lag behind the other side in recovery.

Devastating complications, such as skin slough following a face lift, exposed breast implants, and nipple-areola loss require a more prolonged plan for recovery. Fortunately, these complications are extremely rare and are often associated with predisposing factors such as smoking. These patients require a great deal of attention. We naturally have an instinct to avoid unpleasant situations and circumstances, but these are times when our patients need us to be there for them. These patients must be seen on an almost daily basis. If a strong bond already exists between the patient and the surgeon before the complication develops, this will have a positive influence on the outcome. However, if the surgeon's relationship with the patient was already less than ideal, these complications will serve to further undermine the relationship and result in an unhappy situation for both the patient and the physician. This is when people become angry and seek legal advice, especially if the complication adds an additional financial burden to the patient. It may be tempting to abandon such a patient and to blame him or her for the complication, but it would be unwise. If you absolutely cannot continue with the patient, have a partner or trusted colleague assume the care at your expense.

When I have been able to explain the reason for the complication, I have found that patients have not only been surprised by this explanation but also have appreciated my candor. This communication has further improved our physician-patient relationship and the patient's confidence in me. To do anything less will confirm the impression that "the medical profession covers up errors."

There is no question that by offering to continue working with the patient to correct a complication, you send a reassuring message. I comfort patients by telling them that I have seen these complications and know how to take care of them, and I will not stop until we are both happy with the outcome.

The Dissatisfied Patient

Dissatisfied patients come in two varieties—your own and those of your colleagues. Despite our best efforts in preparing and evaluating our own patients, screening them, and discussing risks and complications and realistic expectations, we still have patients who are not satisfied with their outcomes. Even though these patients may have an average or good result, they are just not happy. This dissatisfaction may be the result of inadequate or even poor communication between the surgeon and patient or patient expectations that were not met. Such patients are extremely difficult to deal with and may never be satisfied. They will exhaust you and test your patience and that of everyone in your office. They also have access to the Internet and the numerous websites that grade or evaluate doctors. They have the freedom to say anything they want about you, your staff, and their result. There are no checks and balances, and it is difficult, if not impossible, to respond to these allegations or comments

once they have been posted. Although most of the time these comments are posted anonymously, most surgeons have a good idea who the patient may be, but are bound by privacy rules from commenting. The best way to deal with these patients is not to operate on them, and with maturity and experience, one should be able to identify them.

One of the most challenging problems in clinical practice is dealing with a colleague's dissatisfied patient. If the patient has an identifiable problem that is correctable and the colleague has referred the patient to you for that purpose, this represents a relatively straightforward situation, since all three parties are involved. However, most of the time the patient is self-referred and would prefer that you not contact the original surgeon.

I evaluate these patients in the same manner that I evaluate any patient. I then explain to them that the problem is correctable and how I would do it. I also explain to them that I am flattered and honored that they have chosen to consult with me, and I take that as an indication of their confidence in me as a surgeon. If the problem is a recognized and not uncommon complication or sequela of the procedure, such as implant malposition or even lid retraction, I explain that I have seen similar complications in my own patients. If I am familiar with the other surgeon and believe that he or she could just as easily correct the problem, I encourage the patient to return to the original surgeon, who may do the revision or correction at no charge or at a discount. I explain that I would not charge my own patients for a similar revision. If the patient does not wish to return to the other surgeon, he or she will usually respond, "He doesn't think there is a problem," "I can't communicate with him," or "He says there is nothing else he can do." I then tell the individual that I would have to charge my full fee for the revision and that it may take more than one procedure. I do ask all patients to have copies of their records forwarded to me, and I ask their permission to communicate with the other surgeon. If the patient does not grant permission, then it would be a breach of his or her privacy to obtain the files, complicating the situation and putting me in an awkward position with my colleagues. These are extremely delicate situations, often involving litigation. It is paramount that the patient's best interests be considered first and that everything possible be done to correct the problem, even at the risk of affecting a collegial relationship. It is important to emphasize that complications do not necessarily indicate a deviation from the standard of care and to refrain from inflammatory comments such as "This is the worst I have ever seen," or "Who did this to you?"

We are physicians and well-trained surgeons, highly skilled in the procedures we perform. Communication skills, however, were never part of our medical school or residency curriculum; we were not taught bedside manner. Yet communication and bedside manner are as important as our skills in the operating room. Our patients expect more than good results; they like to be listened to and cared for. They want a sur-

geon who is responsive and makes them feel valued and respected. Good results and satisfied patients will do far more than any advertising program to promote and grow a practice.

Concluding Thoughts

The practice of cosmetic medicine and aesthetic surgery is satisfying and rewarding for the surgeon. I am excited that it continues to evolve, and it is imperative that we adapt to these changes so that we can provide the best for our patients. To our patients, aesthetic treatments are not a necessity but the fulfillment of a personal goal; therefore their experience must be satisfying and rewarding as well. This is a partnership that at its best works smoothly and effectively for all involved.

In this chapter I have shared my approach, but in truth it is *our* approach—my partners and staff are all intimately involved in making the experience for our patients a positive one. Time spent with the patient by the surgeon and the staff is time well invested. This is especially true today, when our patients have access to all kinds of information on the Internet. Our goal is to establish a long-term and trusting relationship with our patients. We nurture an environment in which our patients can feel that they are among friends when they visit us in our office. Patient satisfaction is the best form of marketing available to us. Such patients are our best source of referrals and will themselves return if the initial experience was one worth repeating.

Clinical Caveats

A well-informed patient is a happy patient.

A well-motivated patient is a happy patient.

Eliminate postoperative financial surprises, or at least warn the patient about them.

Listen to your patients.

Learn to say “no.”

Spend time with your patients.

Respect the patient’s privacy.

First impressions last.

Your website is the face of your practice to the world.

The Internet can be a friend or foe.

CHAPTER 2

Patient Safety in Aesthetic Surgery

V. LEROY YOUNG

New concepts and advances in technology accumulate so quickly these days that much of what plastic surgeons now need to know was probably not covered in their days of medical school or residency. This applies particularly to patient safety, which is becoming a medical discipline all to itself. Evidence is collected from multiple specialties—including anesthesiology, cardiology, pulmonology, endocrinology, psychology, hematology, and infectious disease—and guidelines or recommendations are developed based on that evidence.

If we plastic surgeons cannot keep up with reading our own specialty journals, when are we supposed to delve into those from other disciplines? Yet that is what we must do to keep our patients safe during what are typically elective procedures. Failure to protect our patients from medical harm may lead to consequences ranging from relatively minor postoperative vomiting or a small infection to a deep venous thrombosis (DVT) that produces lasting disability to the worst outcome of all—death.

The movement to improve patient safety began in 1999, when the Institute of Medicine issued its report, *To Err Is Human: Building a Safer Health System*. The report, which focused on the types and frequency of errors associated with the delivery of health care, defined a medical error as “the failure to complete a planned action as intended or the use of a wrong plan to achieve an aim.” An adverse event was described as “an injury caused by medical management rather than by the underlying disease or condition of the patient.” The public, medical professionals, and government agencies were shocked by some of the IOM’s findings, including the fact that more than half of surgical adverse events are preventable.

Some preventable surgical errors arise from policies and others from personnel who deliver the care. Whatever the root cause, the surgeon is ultimately responsible. Consider the example of a patient undergoing an abdominoplasty who does not receive chemoprophylaxis to prevent a blood clot and dies of a pulmonary embolism (PE) several days after she is sent home. If the surgeon had followed regularly updated expert recommendations for the use of chemoprophylaxis, this PE might have been averted. Surgeons who claim ignorance of a safety practice that would have prevented a complication are not in a defensible position, nor are those who choose to ignore evidence-based recommendations because they think they know better.

After the IOM report, the professional societies of physicians, nurses, technologists, and other groups began to disseminate patient safety information to their members. Federal agencies and associated groups also make important contributions to the patient safety movement, and their websites contain valuable resources. Some of the partners for improving the quality and safety of health care include the following:

The Agency for Healthcare Research and Quality (AHRQ), part of the U.S. Department of Health and Human Services that takes the lead in evaluating patient safety and health care outcomes (www.ahrq.gov)

The Centers for Disease Control and Prevention (CDC) (www.cdc.gov)

The Centers for Medicare and Medicaid Services (CMS) (www.cms.gov)
The Joint Commission (www.jointcommission.org)
The American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF) (www.aaaasf.org)
The National Surgical Quality Improvement Program of the American College of Surgeons (www.acsnsqip.org)
The Institute for Healthcare Improvement (IHI) (www.ihl.org)
The World Health Organization (WHO) (www.who.int)
The National Patient Safety Foundation (NPSF) (www.npsf.org)

Some of these groups have developed and continually revise evidence-based measures that help streamline and standardize processes, decrease the variability of delivering health care, and improve patient outcomes. More and more, those organizations responsible for the accreditation of hospitals as well as outpatient and office-based surgery centers follow the evidence-based safety recommendations when measuring facility compliance.

One example of an approach to guideline development is the Surgical Care Improvement Project (SCIP), which was formed as a collaborative effort between CMS and the Joint Commission in 2003 with the goal of reducing preventable surgical complications that have a high frequency and cost. The work of groups like this makes issues such as prevention of surgical site infections and venous thromboembolism (VTE) important measures of quality care, facility performance, and patient outcomes in the surgical setting.

Improving Patient Safety in Plastic Surgery

The amount of information available to make our patients safer during encounters with health care is almost overwhelming. Although plastic surgeons are responsible for knowing at least the most basic recommendations for keeping patients safe during surgery, these recommendations are continually evolving and changing as evidence accumulates about safety issues. For example, at least some of the information in this chapter will likely be outdated by the time this volume is published. However, we are still responsible for knowing current safety standards not only for the facilities where we work but also for our states and the national credentialing organizations. We are helped in this by the national plastic surgery professional associations—the American Society for Aesthetic Plastic Surgery (ASAPS) and the American Society of Plastic Surgeons (ASPS). Recently they have developed requirements for earning safety-related CME credits to retain board certification, which should have the effect of forcing plastic surgeons to keep current with changes. Some of the most important patient safety concerns related to plastic surgery are briefly described in this chapter.

Prevention of Surgical Site Infections

Infection prevention efforts must be directed in multiple directions. Although surgical site infections (SSI) are a serious problem, so are infections spread by simple contact with a health care facility. Health care–associated infections have become such a problem that in 2008 Medicare began refusing to pay for many hospital-acquired infections. Relatively simple measures can make a real impact, such as instituting contact precautions, disinfecting the patient care environment and equipment, and complying with hand hygiene guidelines established by the CDC or WHO.

Special attention must be directed to the prevention of infections caused by multi-drug-resistant organisms (MDRO), including methicillin-resistant *Staphylococcus aureus* (MRSA), *Clostridium difficile* (CDI), vancomycin-resistant enterococci (VRE), and multidrug-resistant gram-negative bacteria. Although MRSA is perhaps the best-known problem, other organisms pose greater threats, especially resistant gram-negative bacteria and *C. difficile*, which recently overtook MRSA as the leading cause of hospital-associated infections. *C. difficile* infections occur primarily in individuals taking antibiotics. Because bringing a new drug to market takes 8 to 10 years, the introduction of new antibiotics will not come soon, and the pipeline is empty.

Practices and processes for reducing the risk of health care–associated infections, including those related to surgical procedures, must address a spectrum of preventive actions, because a variety of factors are known to contribute to SSIs. Some of the risk factors for infection most likely to be encountered by plastic surgeons are shown in the box.

Risk Factors for Infection	
<i>Patient-Related Factors</i>	<i>Treatment-Related Factors</i>
Diabetes mellitus	Abdominal or emergency surgery
Obesity	Operation of 2 hours or more
Recent or current smoking	Inappropriate antimicrobial prophylaxis
Poor nutritional status	Hypothermia in the perioperative period
Older age	Inadequate surgical scrub or skin antisepsis
Previous site radiation	Preoperative shaving
Postoperative anemia	Poor operating room ventilation
Immunosuppression	
	<i>Surgical Technique–Related Factors</i>
	Poor hemostasis
	Failure to obliterate dead space
	Tissue trauma

Antibiotic Use

The overuse of antibiotics is largely responsible for the problem of resistant organisms. It is the responsibility of all physicians to reduce the use of antibiotics in contexts in which they are of dubious value. In fact, many experts believe that antibiotics are unnecessary for clean surgeries without implants, which encompasses most procedures that plastic surgeons perform, but this issue is still being debated. All plastic surgeons should follow the evidence-based guidelines for administering antibiotics in the surgical setting. For many, this will require changing long-standing behaviors, which is never easy. However, the organizations that evaluate the clinical evidence and establish recommendations for reducing the rate of SSIs all agree on antibiotic delivery and timing.

USE THE CORRECT ANTIBIOTIC Surgical patients should receive antimicrobials that target the pathogens most likely to contaminate the wound. The most commonly recommended antibiotic is a first-generation cephalosporin given intravenously in a dose of 1 g (2 g if the patient's weight is more than 73 kg [160 pounds]). Another dose should be given after 3 to 5 hours if the wound has not yet been closed or the patient has lost a large amount of blood. The drugs of choice for patients with a beta-lactam allergy are clindamycin (600 to 900 mg intravenously, repeated at 6 to 12 hours) or vancomycin (1 to 1.5 g intravenously, repeated at 6 to 12 hours).

DELIVER THE ANTIBIOTIC AT THE CORRECT TIME A full dose of cefazolin or a similar antibiotic should be delivered no less than 30 minutes and no longer than 60 minutes before an incision is made. Clinical trials have shown that drug delivery outside this window (too early, at the time of incision, or after the incision) is much less effective in reducing the rate of SSIs than using the appropriate timing. If a tourniquet will be used, the antibiotic must be completely infused before tourniquet application. Vancomycin and clindamycin must be administered slowly, over the course of 1 hour; thus its administration should begin approximately 120 minutes before incision.

ADMINISTER THE ANTIBIOTIC FOR THE CORRECT DURATION Antibiotics should be administered for the shortest effective period possible; a single preoperative dose is usually all that is needed. Most studies have determined that administration of an antibiotic is unnecessary after wound closure. Unless there is a specific reason, antibiotics should be discontinued within 24 hours after the surgical incision. The exception is in cardiac surgery, after which antibiotics may be given for up to 48 hours. Some plastic surgeons typically overuse antibiotics and discharge patients with a 7- to 10-day prescription for antibiotics. This has not been found effective for reducing the risk of SSI; it does, however, contribute to drug resistance. Furthermore, there is no evidence to suggest that antibiotics should be given as long as drains are in place.

In addition to the guidelines for using the right drug at the right time, some other measures for reducing the risk of SSIs relate to proper hair removal, glucose monitoring, hypothermia prevention, and smoking cessation.

Hair Removal

Hair removal is unnecessary for most surgeries. If it is required, all infection prevention guidelines agree that shaving should be avoided, because it significantly increases the risk of SSI, with some studies reporting almost a tenfold increase. A razor makes microscopic cuts in the skin that invite bacterial growth. Many experts recommend that all razors be removed from surgical areas. When necessary, hair should be removed with electric clippers or a depilatory immediately before surgery. Patients should be instructed not to shave during the 2 weeks before a surgery.

Glucose Control

Plastic surgeons do encounter patients with type 1 and type 2 diabetes in their practices, and they should therefore understand the importance of preventing hypoglycemia and hyperglycemia in the perioperative period. Maintaining tight glycemic control may shorten recovery time and the time spent in the postanesthesia care unit (PACU). More importantly, for patients with and without diabetes, hyperglycemia before, during, and after surgery is significantly associated with an increased rate of SSIs and wound healing complications, more than a fourfold increase in some studies.

As part of the process for obtaining preoperative medical clearance for surgery, patients with diabetes should have their hemoglobin A1c level measured. The HbA1c test indicates glucose status for the previous 3 months and, according to the American Diabetes Association, the level should be less than 7%. Recent studies, however, suggest a level below 8% has some advantages, but as yet there is no consensus sufficient to change the recommendations. A higher-value HbA1c suggests a need to adjust medications before surgery with the aim of achieving tighter glucose control. The physician who manages the patient's diabetes should be consulted about perioperative management, and, if warranted, should devise a plan to adjust the timing and dosing of antihyperglycemic medication—insulin or oral—starting the day before surgery.

Preoperative staff must be aware when diabetic patients are expected, especially since they will have been NPO for several hours. These patients should be scheduled for the first surgical slot of the day. As soon as a patient with diabetes arrives at the surgical facility, the blood glucose level should be measured and insulin administered if the glucose level is 180 mg/dl or higher. Patients with insulin pumps may be encouraged to manage their pumps when conscious. Intraoperative hyperglycemia is common and blood glucose must be monitored throughout the perioperative period and treated with insulin. The common recommendation is for type 1 diabetics to be given insulin if blood glucose exceeds 140 mg/dl. Patients with type 2 diabetes can tolerate higher glucose levels, up to 200 mg/dl.

Plastic surgery can be safely performed in patients with diabetes, but surgeons are advised to seek guidance from physicians who know much more about diabetes management in the perioperative period.

Hypothermia Prevention

Since at least the mid-1990s, unplanned perioperative hypothermia has been viewed as a major risk factor for surgical site infections and other wound healing complications in patients undergoing colorectal surgery. In 2010, groups that develop and apply standards for improving patient safety and tracking outcomes (including SCIP, the Joint Commission, CMS, and IHI) expanded the recommendation for preventing hypothermia to include all surgical patients receiving general or neuraxial anesthesia for a procedure lasting 1 hour or longer. Most guidelines suggest that normothermia be maintained with active warming methods, which consist of forced-air warming systems, circulating warm water garments, and polymer-based conductive fabric blankets. Regardless of the method used, its effectiveness cannot be measured unless the core temperature is being monitored, preferably from the pulmonary artery, distal esophagus, tympanic membrane, or nasopharynx. The skin, axilla, and mouth are the least accurate measurement sites.

Hypothermia, which is defined as a core body temperature lower than 36° C (96.8° F), has serious consequences, including a threefold increase in wound infections, delayed wound healing, a higher risk for bleeding and transfusion need, cardiac events, altered drug metabolism, more difficulty obtaining hemostasis, coagulopathy disorders, and longer times in the PACU. Some studies also show that hypothermia contributes to postoperative nausea and vomiting. Surgical patients who are not actively warmed during the perioperative period almost always become hypothermic. The three stages of hypothermia development help explain why:

1. The body starts redistributing heat from the core to the periphery during the first hour of general or regional anesthesia. After 1 hour the patient is hypothermic.
2. The linear core temperature steadily declines.
3. The core temperature reaches a plateau between hours 2 and 4 of surgery with general anesthesia. This plateau does not develop with regional anesthesia and the core temperature continues to decline.

When hypothermia is allowed to develop, returning to core normothermia may require 4 or more hours. Furthermore, waiting until a patient's temperature begins to fall before initiating active warming measures is too late.

Unless preventive measures are instituted, several plastic surgery procedures place patients at high risk for developing hypothermia and all its harmful effects, especially procedures that require exposure of large body surface areas (for example, liposuction, abdominoplasty, and lower body lift). Postanesthetic shivering is common in hypothermic patients and carries its own consequences. Shivering seems to

magnify postoperative pain and may play a role in postoperative nausea and vomiting. Bruising and/or hematoma may occur more often with shivering, which could compromise the results of facial procedures such as face lift or blepharoplasty. Hypothermia definitely complicates perfusion of any type of flap, and the addition of shivering is likely to impair blood supply even more. For these reasons, postoperative shivering should be treated aggressively with an active preventive measure.

Multiple techniques are available for preventing hypothermia in the perioperative period. All clinical trials agree that *active warming* is necessary (using forced-air, circulating water, or conductive fabric blankets). Moreover, prospective, randomized, and controlled studies indicate that the key to maintaining normothermia is prewarming with an active method for about 1 hour before surgery begins. Surgeons should use the evidence-based interventions that are proven to be most protective of patients by extending active warming during and after surgery. *Passive warming* methods may be used to supplement the active ones, especially when procedures place patients at increased risk, as long as one understands that none of these can add much heat content to a patient. Frequently used passive techniques include insulation of patients with standard or even heated blankets or drapes, raising the ambient temperature of the operating room, and warming irrigation, intravenous, or infiltration fluids. Warmed fluids should be delivered at core temperature (37° C [98.6° F]). A temperature higher than 43° C (109.4° F) carries a risk of burns.

Recommended Practices for Hypothermia Prevention During General or Neuraxial Anesthesia

1. Actively prewarm patients in the preoperative area for approximately 1 hour with forced-air heating, a resistive-heating blanket, or circulating water garment.
2. Keep the ambient temperature of the operating room at approximately 22.8° C (73° F).
3. Monitor the core temperature throughout general and neuraxial anesthesia, and respond to temperature drops with active warming methods.
4. Cover as much body surface area as possible with blankets or drapes to reduce radiant and convective heat loss through the skin.
5. Actively warm patients intraoperatively with forced-air or other technology to prevent heat loss and add heat content. Rearrange the cover or covers if patients are repositioned so as much surface area is warmed.
6. Minimize repositioning time as much as possible so an active warming method can be quickly continued.
7. Warm intravenous fluids and/or infiltration fluids, especially if large volumes are used, so that they are 37° C (98.6° F) when they enter the body. This may require a warming setting of 40° C to 42° C (104° F to 107.6° F), depending on the length and diameter of the tubing/cannula. For large incisions, consider warming the irrigation fluids.
8. Aggressively treat postanesthetic shivering with a forced-air heater or resistive-heating blanket and consider pharmacologic intervention.

Achieving the goal of always maintaining normothermia will require a change in habits. Fortunately, keeping patients warm is relatively simple and can easily be incorporated into the perioperative routine.

Smoking Cessation

Today most plastic surgeons ask patients who smoke or use tobacco in another form to stop before surgery. The majority of prospective studies conducted on this issue indicate that smokers have a statistically significant increased risk of surgical complications, especially infection and delayed wound healing, than nonsmokers and former smokers. This may be a result of the fact that multiple agents contained in smoke decrease the amount of oxygen available to tissues. Nicotine, for example, is vasoactive and induces endothelial injury, inhibits capillary flow, and decreases epithelialization. Carbon monoxide causes tissue hypoxia. Some debate exists about whether heavy smoking is more risky than light smoking, and whether a former smoker has a complication rate more like a current smoker or one who has never smoked. However, just about everyone agrees that procedures involving flaps or extensive undermining are much riskier for smokers. Aesthetic results are also more likely to be compromised.

Most studies that compare complications in smokers and nonsmokers do not verify smoking status, which is unfortunate, because patient self-reporting is unreliable. Patients either say they are not smoking when they are, or they underreport the amount they smoke. The safest way to address this problem is for surgeons to test for recent smoking before and after surgery. The most common and inexpensive method for verifying smoking status is to measure the levels of cotinine in the urine, saliva, or blood. Cotinine persists in urine for up to 4 days and test results are available within about 10 minutes, at a cost of approximately \$10 per test.

Plastic surgeons have every right to refuse to perform surgery on patients who smoke, especially since not smoking makes surgery safer. A good approach to make certain someone is not smoking is to test for cotinine a few weeks before surgery and again on the morning of surgery. If a test is positive, the procedure should be delayed. Another test a few weeks after surgery proves whether someone has smoked recently. If that test is positive, the documented result might prove valuable if postoperative complications develop. The amount of time a smoker should abstain from smoking is currently unclear, but the CDC recommends 4 weeks before surgery; 2 months would be even better. By 30 days after surgery, fibroblast proliferation, collagen production and deposition, and reepithelialization have reached their peak. Postoperative abstinence is especially important if a smoker had little or no warning before surgery, as is often the case with procedures such as breast reconstruction, traumatic injury repair, or cancer resection.

Prevention of Venous Thromboembolism

In 2008, the Surgeon General's office issued a report identifying deep venous thrombosis and pulmonary embolism as among our most serious public health problems that demand attention, concerted action, and research to reduce their prevalence. According to the Surgeon General, approximately 20% of people with a PE die almost immediately, and a fatal PE is often the first symptom of DVT. The period of highest risk for a fatal PE in surgical patients is within 3 to 7 postoperative days, a point at which many surgical patients are at home, but the risk for postoperative VTE remains elevated for 3 months.

VTEs that occur in association with health care—and especially surgery—should be the easiest to prevent, yet they continue to occur at alarming rates. The Million Women Study recently reported its analysis of health records for 947,454 middle-aged women in the United Kingdom regarding the incidence of VTE during the first 12 weeks after surgery and compared it to matched middle-aged women who did not have surgery. The study determined that 1 in 140 women who had inpatient surgery was hospitalized for or died from VTE, and 1 out of 815 women who had outpatient surgery was hospitalized or died because of a VTE in the 12-week postoperative period. For women who did not undergo surgery, the incidence of VTE was 1 out of 6200. These rates seem even more disturbing when we consider that this epidemiologic study could follow only women who were hospitalized with a diagnosed VTE. The number of diagnosed DVTs is believed to represent only about a third (or less) of events, and not all people with diagnosed DVT are hospitalized.

To address the need for information about VTE development, the last several years have seen the publication of educational articles in plastic surgery journals. Although growing numbers of plastic surgeons report using VTE prophylaxis methods, the majority employ only mechanical devices such as graduated compression stockings (GCS) or intermittent pneumatic compression (IPC) applied to the calves or feet. The value of GCS is highly questionable, because they are completely passive devices and are unlikely to be fitted properly. In 2008, the eighth edition practice guidelines developed by the American College of Chest Physicians (ACCP) departed from its previous recommendations and determined that mechanical prophylaxis used alone is appropriate *only* for surgeries lasting less than 1 hour or for patients who are at very high risk for bleeding, as would be the case for a patient with an inherited or acquired thrombophilia. For other surgical patients, mechanical prophylaxis may be used in conjunction with an anticoagulant but is not recommended as the primary means of VTE prevention. According to the ACCP, the efficacy of mechanical prophylaxis methods has not been demonstrated in well-designed clinical trials; the variations in device sizes and pressures make IPCs difficult to study, and determining

whether the devices are used properly and consistently is difficult to establish. Because IPCs work primarily in the calves, they also may be unable to prevent the most dangerous clots, which propagate proximally and may be fatal if they reach the lungs. Despite these problems, IPCs are not likely to cause harm, although they are contraindicated in patients with peripheral vascular disease. If ordered, IPCs should be started in the preoperative area and worn until the patient is fully ambulatory.

Before 2008, the ACCP based its recommendations for VTE prevention on individual risk factors, an approach that has been presented in most of the plastic surgery literature related to VTE. A surgical patient's risk for VTE is determined by assigning points for every risk factor a patient has; the total number of points indicates the level of risk (low, moderate, or high) and therefore the type of VTE prophylaxis. The 2008 guidelines departed from this model and instead based recommendations according to type of surgical procedure rather than individual risk factors.

The change was made because randomized clinical trials of VTE prevention that provide the evidence for recommendations are based on group risk assignment, such as VTE incidence in patients undergoing total hip replacement, abdominal procedures, bariatric surgery, etc. Even though the new guidelines discuss a variety of surgical disciplines, the conclusions of the guidelines are similar for all procedures: *Surgery patients should receive either low-molecular-weight heparin (LMWH), low-dose unfractionated heparin (LDUH), or fondaparinux for VTE prophylaxis unless they are undergoing a minor procedure or have a high risk of bleeding.*

Even though evidence from other surgical specialties indicates that postoperative anticoagulants significantly reduce the incidence of VTE, have a positive benefit-to-risk ratio, and improve patient outcomes, chemoprophylaxis remains underused in plastic surgery. However, many plastic surgery patients tend to have multiple risk factors that place them at moderate to high risk for VTE. Some of the most common risk factors encountered are these:

- Major surgery that lasts longer than 1 hour (the risk rises with each hour)
- Age 40 years or older (the risk rises as age rises)
- General anesthesia
- Use of oral contraceptives, hormone replacement therapy, or selective estrogen receptor modulators (used for treatment of breast cancer and osteoporosis)
- Obesity
- Malignancy (active or in patient history)
- Abdominal surgery (carries higher risk than most other types of surgery)
- Varicose veins
- Smoking

Many plastic surgeons are reluctant to use anticoagulants for fear of causing bleeding complications that may compromise results. However, most meta-analyses and placebo-controlled randomized clinical trials from other surgical specialties have found that the risk of clinically important bleeding does not increase if drug instructions are followed correctly. According to the Joint Commission and the Surgical Care Improvement Project (SCIP), a bleeding risk that is considered normal for surgery is not an acceptable reason for not administering anticoagulants.

As a general rule, anticoagulants should be started at least 6 to 8 hours after surgery. One common approach is to use a drug that can be subcutaneously injected by the patient once a day beginning the morning after surgery. For the purpose of VTE prevention (not treatment) enoxaparin is packaged in a 40 mg dose, and fondaparinux syringes come in a 2.5 mg dose. The recommended duration of anticoagulant use is between 7 to 10 days to ensure that patients are protected when the risk of VTE is highest, during the first postoperative week.

The need for anticoagulants seems highest in procedures that involve the lower trunk because patient positioning invites venous stasis of the lower extremities, and increased intraabdominal pressure decreases blood flow in the femoral vein. In an analysis of 2.4 million outpatient surgeries, the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF) determined that the risk of death is 10 times higher in outpatient abdominoplasty patients than for any other outpatient procedure. Although plastic surgeons have not yet conducted the types of prospective randomized clinical trials needed to evaluate the effectiveness of chemoprophylaxis in plastic surgery patients, some surgeons have begun to report data on this question, particularly with respect to lower body–contouring procedures. In comparisons of patients receiving anticoagulants with those receiving mechanical prophylaxis only, most recent studies (but not all) have found statistically significant lower rates of VTE in patients receiving chemoprophylaxis.

With respect to bleeding, some studies have seen increased postoperative bleeding in patients who received LMWH compared to mechanical prophylaxis. Among lower body contouring patients, the incidence of hematoma and need for transfusion were significantly higher when anticoagulants were used. However, other studies have found no significant differences in bleeding complications when patients receiving LMWH were compared with controls (no treatment).

Patients with cancer are also known to be at increased risk for VTE. When compared to surgical patients without cancer, those with cancer have at least twice the risk of developing a DVT in the postoperative period and three times the risk of a fatal PE. Patients receiving chemotherapy have a risk for VTE that is 6 times higher than patients without cancer. Other treatment modalities (selective estrogen receptor mod-

ulators like tamoxifen, angiogenesis inhibitors, and aromatase inhibitors) are also associated with increased VTE risks. Plastic surgeons often treat cancer patients and must consider the use of chemoprophylaxis in this patient population, especially when performing reconstruction with flaps. One study of TRAM flap patients who received D-dimer tests and lung scans to look for VTE found that 17% who received no chemoprophylaxis had asymptomatic PEs, compared with no patients who received LMWH.

The debate about using chemoprophylaxis in plastic surgery will likely continue for the foreseeable future. Growing numbers of plastic surgeons seem to be adopting the use of anticoagulants for patients undergoing lower body contouring procedures such as abdominoplasty (with or without additional procedures), circumferential body lift, panniculectomy, and large-volume liposuction in the lower trunk or thighs. No studies have yet reported serious bleeding complications that were difficult to manage in these patients. Thus, unless a patient is at high risk of excessive bleeding, chemoprophylaxis currently seems to possess greater benefits than risks for many plastic surgery patients. The issue may ultimately be resolved by groups such as the Joint Commission, which has recently adopted guidelines regarding the timing of chemoprophylaxis for VTE prevention among inpatient surgical patients as one of its performance measures for determining a facility's quality of care during the accreditation process.

Prevention of Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is thought to affect up to 70% of surgical patients unless preventive measures are instituted. Although a postoperative complication itself, nausea and vomiting may contribute to additional complications such as hematoma and wound dehiscence following procedures such as face lift, blepharoplasty, breast surgery, or abdominoplasty. PONV may also delay discharge from the surgical facility or lead to unplanned hospital admission. Postoperative nausea and vomiting is often rated higher than pain as a source of discomfort associated with surgery and can erode patient satisfaction.

Of all the patient safety concerns, PONV is perhaps the easiest to prevent in most patients. Important risk factors for developing PONV are female gender, a history of PONV or motion sickness, not smoking, and perioperative opioid treatment. None of these risk factors is unusual in plastic surgery patients, but the risk for PONV rises 20% with each additional factor; for example, a 40% increased risk in patients with two risk factors and 80% when four risk factors are present. The key to prevention and treatment is the use of pharmacologic agents to block neurotransmitters that stimulate emesis. Some of the important receptors implicated in PONV are serotonin (5-HT₃), dopamine, histamine (H-1), neurokinin-1, cholinergic, and inflammatory receptors.

No single receptor antagonist seems to be successful in blocking PONV in patients who have two or more risk factors, but combinations of at least two drugs that target different receptors are known to be effective. When three or more receptors are blocked, PONV can be prevented in up to 90% of patients. As a general rule, the more risk factors a patient has, the more prophylactic antagonists will be needed. Commonly used antagonists include combinations of a serotonin blocker (ondansetron), an antiinflammatory (dexamethasone), a dopamine antagonist (droperidol), and/or an antihistamine (diphenhydramine) delivered intravenously, with some given preoperatively and others near the end of surgery. A neurokinin-1 receptor antagonist called aprepitant (Emend, Merck & Co., Whitehouse Station, NJ) is a newer alternative that continues to act for 48 hours and is taken in pill form before surgery.

If a patient develops PONV despite preventive efforts, the rescue should be approached using a different class of drug than was used as a prophylactic antiemetic so that a different receptor is targeted. If PONV continues beyond 6 hours after surgery, many drugs could be repeated, except for those that are long-acting, such as dexamethasone, aprepitant, and scopolamine.

Obstructive Sleep Apnea

Elective surgery can be safely performed on patients with obstructive sleep apnea (OSA), which is characterized by intermittent closure or narrowing of the upper airway during sleep that results in a 30% reduction in airflow for at least 10 seconds and reduces oxygen saturation by at least 4%. To plan for potential complications that may arise in OSA patients, the surgeon must first know the condition is present. Unfortunately, estimates suggest that OSA is undiagnosed in at least 80% of individuals who have the disorder. The plastic surgeon must therefore be aware of OSA risk factors, which include obesity (especially with a BMI greater than 35), men older than 40 and women who are perimenopausal or postmenopausal, a neck circumference larger than 17 inches in men and 16 inches in women, a positive family history, and hypertension. Experts speculate that 50% of hypertensive patients have OSA; in addition, 60% to 90% of OSA patients are obese.

Because so many people are unaware they suffer from sleep apnea and deny its symptoms, the best source for identifying patients with OSA is the spouse or another person who lives in the home. A simple screening tool called STOP has been developed to assist with identifying OSA. Sleep apnea should be suspected in a patient who has two of these four symptoms:

1. Snoring loud enough to be heard through a closed door
2. Tiredness or daytime hypersomnolence (falling asleep easily in a nonstimulating environment, such as watching television or riding in a car)
3. Observed pauses in breathing during sleep
4. Pressure reading or history of hypertension

Diagnosis is confirmed with multiple-channel polysomnography performed in a sleep laboratory. The most important OSA treatments are weight loss, elevating the head of the bed to 30 degrees to 60 degrees, using an oral appliance, and wearing a continuous positive airway pressure (CPAP) device.

Anesthesia Management

Patients with OSA typically require special anesthesia management. If OSA has been diagnosed or is suspected, the anesthesiologist should evaluate the patient before surgery because the airway may be difficult and require fiberoptic intubation. Surgery in an outpatient setting with local or regional anesthetic should be safe, but the facility should have the equipment and expertise to carefully monitor patients and deliver advanced respiratory care if needed. Longer surgeries, especially those which cannot be done with regional blocks or light sedation, should be performed in a hospital.

Extubation should not be done until the patient is fully awake. Postoperative monitoring and attentive staff are essential for recognizing respiratory depression and abnormal heart rhythms. Monitoring should be continued for at least 3 hours longer than patients without apnea would receive, and an overnight stay would be preferable. Patients who used a CPAP before surgery should bring the device to the surgical facility so it can be used in the postoperative period. If possible, the supine position should be avoided; instead, the head of the bed should be elevated to a 30- to 45-degree angle. Patients with OSA are very sensitive to sedatives and opioids, which should be sparingly used or avoided altogether. Supplemental oxygen can help maintain SpO₂ higher than 90%.

Perioperative Beta-blockers and Other Cardiac Issues

It is not unusual to encounter patients with some degree of cardiovascular disease, especially hypertension, in plastic surgery practices. Individuals seeking body contouring after weight loss, obese patients inquiring about liposuction, and women who want to undergo breast reconstruction are among those more likely to be taking beta-blockers. The withdrawal of beta-blockers for surgery has been found to carry a much higher risk of mortality than continuation of the drug. Consequently, the American College of Cardiology/American Heart Association (ACC/AHA) and SCIP recommend that surgical patients who take daily beta-blockers continue the therapy throughout the perioperative period to reduce the risk of cardiovascular complications during and after surgery. If beta-blocker therapy is not continued perioperatively, the surgeon should document the reason (or reasons).

The ACC/AHA also recommends that surgeons *not* order perioperative beta-blockers for all patients in an effort to reduce perioperative cardiac risks. Starting a patient on beta-blockers requires monitoring by a cardiologist, internist, or other specialist. Plastic surgeons are not trained to diagnose and/or treat cardiovascular disease and

should consult with cardiac specialists about patients who have risk factors for major cardiac complications associated with surgery:

- A high-risk operation (intraperitoneal, intrathoracic, vascular)
- A history of ischemic heart disease or heart failure
- A history of cerebrovascular disease
- Diabetes requiring insulin
- A preoperative serum creatinine level above 20 mg/dl

If a patient is taking antiplatelet drugs, such as clopidogrel bisulphate (Plavix) or aspirin, the plastic surgeon needs to know why. Surgery increases the risk of coronary stent thrombosis, especially early after stent placement. Stopping an antiplatelet drug should not be recommended by a plastic surgeon if a stent is present unless the patient's cardiologist approves.

Office-Based Surgery

All board-certified plastic surgeons who perform surgery in their offices have a responsibility to make sure their facilities are accredited by AAAASF, the Joint Commission, or some other recognized credentialing organization. Gaining certification requires meeting certain safety practices and tracking all surgical complications and adverse events. Whenever a surgical patient is on the premises, someone trained in advanced cardiac life support must be present, and all personnel who work in the surgical area should be trained in basic cardiopulmonary resuscitation. The types of routine monitoring and emergency equipment and supplies needed at the facility are usually mandated by accrediting agencies.

In a review that compared surgical outcomes in offices and ambulatory surgery centers in Florida, the risk of adverse incidents and death was 10 times higher in offices than surgery centers. Thirteen deaths occurred in office facilities, only 15% of which had an anesthesiologist present, with only 38% of offices accredited for surgery. This study highlights the fact that a surgeon is not an anesthesiologist. The AAAASF requires that general anesthesia be administered by an anesthesiologist or certified registered nurse anesthetist (CRNA). A surgeon may give intravenous sedation but may not deliver Propofol because it requires careful monitoring.

Evidence-based initiatives such as those that call for changes in infection prevention protocols tend to arise in hospitals first, but they eventually spread to office settings and outpatient surgery centers. Ultimately, quality and performance reporting related to complications will be required by agencies such as AAAASF during a facility's accreditation process. Every site at which surgery is performed should have documented policies and procedures that directly address patient safety concerns. Moreover, those policies should be routinely reviewed and, if needed, modified to

reflect the best evidence available at the time. Sometimes the adoption of guidelines requires changing long-standing habits.

Building a Culture of Safety

In recent years, the value and applications of checklists in medicine, especially surgery, have been proved worthwhile. The measures contained in national guidelines are reviewed and revised as evidence warrants in an effort to reflect the state of the science. Ultimately, such guidelines are used as a way to measure facility quality and patient outcomes.

Another method of improving patient safety is growing in popularity, especially in larger facilities: opting out of safety recommendations. Instead of writing orders to have something done, “opt-out” requires physicians to explain why a safety practice is not being followed. For example, an order does not need to be written for an antibiotic to be administered, but if it was not given—and at the recommended time—the reason must be documented. Some newer recommendations from the Joint Commission pertaining to VTE prophylaxis (both mechanical and pharmacologic) require the surgeon to specify why preventive measures were not ordered; likewise, a bleeding risk considered normal for surgery is not an acceptable reason for not using anticoagulants.

The Surgical Safety Checklist developed by the WHO presents a list of actions that should always be performed by the surgical staff (see p. 52). This protocol, or a variation of it, may be posted in operating rooms around the country, yet it is ignored daily. Although surgeons and other members of the perioperative team know their responsibilities without having to be reminded, preventable errors still occur. Thus reminders are crucial to keeping patients safe.

The Surgical Safety Checklist has been prospectively examined in eight countries at different stages of development before and after the checklist intervention was introduced. The preintervention group consisted of 3733 patients undergoing non-cardiac surgery, and the intervention group had 3955 patients. When the checklist was used, the patient rate of death significantly declined ($p = 0.003$), as did the number of inpatient complications ($p < 0.001$). The reasons for the improvement in patient outcomes may go beyond use of a checklist. In several of the hospitals, adhering to the checklist required changing some systems (for example, when antibiotics are administered before surgery) and behaviors (operating room staff must communicate about the patient during the surgical time-out and again at the debriefing). Designed as a sequence of tasks to perform, the checklist resulted in better team communication and awareness of safety practices.

SURGICAL SAFETY CHECKLIST (FIRST EDITION)

Before induction of anaesthesia

Before skin incision

Before patient leaves operating room

SIGN IN	TIME OUT	SIGN OUT
☐ PATIENT HAS CONFIRMED • IDENTITY • SITE • PROCEDURE • CONSENT	☐ CONFIRM ALL TEAM MEMBERS HAVE INTRODUCED THEMSELVES BY NAME AND ROLE	NURSE VERBALLY CONFIRMS WITH THE TEAM:
☐ SITE MARKED/NOT APPLICABLE	☐ SURGEON, ANAESTHESIA PROFESSIONAL AND NURSE VERBALLY CONFIRM • PATIENT • SITE • PROCEDURE	☐ THE NAME OF THE PROCEDURE RECORDED
☐ ANAESTHESIA SAFETY CHECK COMPLETED	ANTICIPATED CRITICAL EVENTS	☐ THAT INSTRUMENT, SPONGE AND NEEDLE COUNTS ARE CORRECT (OR NOT APPLICABLE)
☐ PULSE OXIMETER ON PATIENT AND FUNCTIONING	☐ SURGEON REVIEWS: WHAT ARE THE CRITICAL OR UNEXPECTED STEPS, OPERATIVE DURATION, ANTICIPATED BLOOD LOSS?	☐ HOW THE SPECIMEN IS LABELLED (INCLUDING PATIENT NAME)
DOES PATIENT HAVE A:	☐ ANAESTHESIA TEAM REVIEWS: ARE THERE ANY PATIENT-SPECIFIC CONCERNS?	☐ WHETHER THERE ARE ANY EQUIPMENT PROBLEMS TO BE ADDRESSED
KNOWN ALLERGY?	☐ NURSING TEAM REVIEWS: HAS STERILITY (INCLUDING INDICATOR RESULTS) BEEN CONFIRMED? ARE THERE EQUIPMENT ISSUES OR ANY CONCERNS?	☐ SURGEON, ANAESTHESIA PROFESSIONAL AND NURSE REVIEW THE KEY CONCERNS FOR RECOVERY AND MANAGEMENT OF THIS PATIENT
☐ NO	HAS ANTIBIOTIC PROPHYLAXIS BEEN GIVEN WITHIN THE LAST 60 MINUTES?	
☐ YES	☐ YES	
DIFFICULT AIRWAY/ASPIRATION RISK?	☐ NOT APPLICABLE	
☐ NO	IS ESSENTIAL IMAGING DISPLAYED?	
☐ YES, AND EQUIPMENT/ASSISTANCE AVAILABLE	☐ YES	
RISK OF >500ML BLOOD LOSS (7ML/KG IN CHILDREN)?	☐ NOT APPLICABLE	
☐ NO		
☐ YES, AND ADEQUATE INTRAVENOUS ACCESS AND FLUIDS PLANNED		

THIS CHECKLIST IS NOT INTENDED TO BE COMPREHENSIVE. ADDITIONS AND MODIFICATIONS TO FIT LOCAL PRACTICE ARE ENCOURAGED.

An analysis of closed malpractice claims determined that failures in communication can lead to injury in surgical patients. In addition, root cause analysis has revealed that communication errors played a role in 80% of wrong-site surgeries reported to the Joint Commission. The factors most commonly associated with a breakdown in communication are ambiguity about responsibilities in 73% of cases and “status asymmetry” in 74% (the surgeon has the highest status in the operating room). A good opportunity for soliciting input from all team members is a preoperative briefing, the surgical time-out, or a debriefing at the end of a procedure. A surgical time-out that uses a checklist is known to reduce failures in team communication. For example, before a time-out intervention was introduced in one study, 3.95 communication failures per procedure were documented by trained observers; after instituting the intervention, the failures declined to 1.31 per procedure ($p < 0.001$).

Many elements of an effective preoperative briefing (as staff gather in the operating room) or time-out (just before making the incision) have been identified. The obvious elements are staff introductions and identification of the patient, the procedure, and the laterality (if applicable). This pause should also outline the surgical plan and its critical steps, as well as potential patient safety risks or hazards and equipment problems. Identification of issues that might arise in advance can prevent or minimize adverse events. In addition, any medical concerns, such as a comorbid condition, should be specified and patient positioning explained.

Checklists and Guidelines

Anesthesiology used to have one of the highest rates of error in medicine, estimated to be 25 to 50 per million. Development of standardized protocols and equipment has reduced the error rate in anesthesiology to 5.4 per million. Anesthesiologists took their cue from the written protocols and checklists used by such high-risk professions as aviation, the military, and nuclear power engineering. Checklists—concise lists of action items—are essential for ensuring that patient safety procedures are followed. Some may think that going through a checklist and written protocol multiple times a week is boring, repetitive, and a waste of time and effort. Do we want airline pilots to have similar complacent attitudes, or do we want all checklists to be completed before take-off and landing? Checklists can have great value when tasks become so automatic that nobody pays attention.

Just as each patient is an individual, every surgery is a unique and complex process, even if the procedure is simple. At any point a crisis can arise, and a life can be lost or damaged. Every person in an operating room has his/her individual responsibilities, and all are focused on different tasks that must be completed at the same time. Staff must also remain aware of the “big picture” and know what everybody else in the room is doing. The surgeon has the greatest responsibility in this process because he or she will ultimately receive the praise or the blame.

Despite their limitations, several guidelines that span the time between initial screening and postoperative follow-up are presented below. Although more extensive than the WHO Surgical Safety Checklist, these guidelines do not pretend to be all inclusive. It is hoped that these guidelines may serve as prompts for important issues plastic surgeons should think about.

Getting Patients Ready for Surgery

An emphasis on ensuring a patient's safety should begin with the initial consultation, when the surgeon first meets a patient and begins to establish a relationship. The surgeon and his/her staff must explain that a patient's own safety may depend on the extensiveness and truthfulness of answers to questions about medical and surgical history. For example, patients rarely give you their actual weight, and some smokers will not tell you they smoke. One reason that patients are sometimes less than truthful is because they do not want to give the surgeon a reason to refuse to perform a desired procedure.

Patients may be more accurate with health and medication history if they complete medical/surgical questionnaires at home rather than in the waiting room. Once you have the health history questionnaire, the physician must not glance through it and assume that this provides all that is necessary of a patient's medical history. Probing questions should be asked about everything checked "yes" on the form, and why all of a patient's medications were prescribed. It is important to determine whether other medications have been prescribed but not taken or were taken in the past but are no longer needed. Listening closely to what the patient says and asking follow-up questions when necessary are essential. For example, if a patient mentions that a parent or sibling once had a problem with general anesthesia, the physician should ask for an explanation. If patients can recall only sketchy details, they should be asked to provide the information when they learn more. Such information could prevent the development of a potentially fatal episode of malignant hyperthermia.

The items listed in the box are essential to preparing patients for surgery.

Text continued on p. 59

Suggested Guidelines for Preparing Patients for Surgery

Obtain a complete medical and surgical history. Consider asking what, where, when, and why questions.

Record all medications currently taken or taken in the recent past. Include over-the-counter drugs and supplements (some of which can affect blood-clotting). Ask whether any medications have changed every time a patient is seen in the preoperative period.

Stop estrogen-containing drugs (birth control and hormone replacement therapy) 4 weeks before major surgical procedures because they raise the risk for DVT.

Stop all selective estrogen-receptor modulators (used for breast cancer or osteoporosis prevention and treatment) at the time recommended by the manufacturer of the specific drug. This may vary from a few days to a few weeks.

Some patients who take clopidogrel, daily aspirin, or other antiplatelet drugs may need to stop these medications 1 to 2 weeks before surgery. Others should continue them throughout the perioperative period. Consult with the prescribing physician to determine the wisest option. Antiinflammatory drugs also elevate the risk of bleeding and ideally should be stopped 2 weeks before surgery.

Patients who are 50 years of age or older should obtain an electrocardiogram and the following laboratory tests: complete blood cell count, basic metabolic panel, prothrombin time, and partial thromboplastin time. Test results from within the past year may be acceptable if there have been no health changes.

Order blood tests needed to evaluate the nutritional status of patients who have had bariatric surgery.

Consult with specialists if a patient has any chronic condition to determine how surgery might impact the disease or how their conditions might influence perioperative care. This is especially important for cardiovascular and pulmonary disorders, including hypertension and asthma.

Determine whether a patient with a chronic condition should have surgery in an office setting versus ambulatory center versus hospital operating room.

Have patients with chronic illnesses, massive weight loss, or any medical issues you are not comfortable with obtain medical clearance for surgery from the primary care physician.

Determine whether a patient's expectations are realistic. Get psychiatric clearance if the patient has a history of serious pathology. For those suffering from depression (now or in the past), make sure the disease is well controlled (contact the mental health professional or ask for a letter of clearance).

Have patients with diabetes get a hemoglobin A1c test, which measures glucose status for the past 3 months. Consult with the physician who manages the diabetes to determine what modifications in the insulin or other medication regimen might be needed the night before and day of surgery.

Explain the need for abstinence from smoking for 1 month before and after surgery and tell patients they will have a urine cotinine test at least 2 weeks before surgery, the morning of surgery, and at some point after surgery to verify that they are not smoking.

Be attentive to indications that a patient may (knowingly or unknowingly) have obstructive sleep apnea. Patients diagnosed with OSA should have a preoperative consult with an anesthesiologist.

Tell patients who use a continuous positive airway pressure (CPAP) device for OSA at home to bring the unit to the surgical facility for use after the procedure.

Instruct patients not to shave the surgical area for 2 weeks before surgery as a way to lower risk of infection.

Check for bacterial and yeast infections in the skin folds of massive-weight-loss patients and treat such infections before surgery with fluconazole or nystatin.

Make certain that all consent documents have been fully discussed and are properly signed.

Suggested Preoperative Preparation Guidelines

Patients should shower with a 4% chlorhexidine gluconate (CHG) product on the morning of surgery to reduce microbial colony counts. Those with skin folds should additionally shower the evening before surgery. A second cleansing of the operative site should be performed in the preoperative area using cleansing wipes that contain 2% CHG.

Verify the patient's current medications and identify patients with allergies.

Mark the patient while he or she is awake to confirm the correct operative site.

Perform urine cotinine testing or some other reliable test to ensure the patient has not smoked if appropriate to the surgical procedure.

Attach the patient's pulse oximeter and other vital signs monitors and make sure they function properly.

Begin hypothermia prevention 45 to 60 minutes before surgery by prewarming the patient with a forced-air heating blanket or some other active warming device. (Warmed cotton blankets are not sufficient.)

Begin DVT/PE prophylaxis with intermittent pneumatic compression (IPC) or sequential compression devices (SCD) at least 30 minutes before surgery.

When indicated, administer cephalosporin or another appropriate parenteral antibiotic no sooner than 30 minutes or longer than 60 minutes before the incision. Adjust the dosage according to patient weight. Clindamycin is usually preferred for patients allergic to penicillin. If clindamycin or vancomycin is used, its administration should begin 2 hours before incision. Timing of the dose may depend on whether a surgical delay is possible.

Begin the drug protocol for prevention of postoperative nausea and vomiting (PONV) in patients with two or more risk factors. High-risk patients may benefit from a prescription for aprepitant, a 40 mg pill taken the morning of surgery that provides 48 hours of protection.

All patients with diabetes, especially those who have been without oral medication or insulin since the evening before, must have their glucose checked on arrival in the preoperative area. Tight glucose control (80 to 120 mg/dl) should be maintained with insulin titrated to blood sugar levels throughout the perioperative period or according to his/her physician's advice.

If hair removal is necessary, have the nurse use clippers rather than a razor.

Suggested Intraoperative Guidelines

Set the operating room temperature to approximately 23° C (73.4° F) to help maintain normothermia.

Continue IPCs or SCDs for DVT prophylaxis.

Place the patient beneath a forced-air warming blanket to actively warm nonsurgical areas and maintain a body temperature of 36.1° C (97° F) or higher throughout surgery. Consider warming the irrigation, tumescent, and intravenous fluids so they are delivered at approximately 37° to 41° C (98.6° to 105.8° F). If the patient is repositioned during surgery, continue active warming methods after each position change. Use proper padding and gel heel protectors to prevent traction, pressure, or nerve injury. Recheck with every change in patient position.

Have preoperative photographs and/or imaging results posted for reference.

Reinforce the patient's markings.

Place a Foley catheter if needed (large-volume liposuction, or major body contouring such as a lower body lift).

Take the surgical time-out as close as possible to making the incision, when all staff are present and are not distracted by other matters. Use a standard time-out routine and make certain all operating room staff are involved and all equipment and supplies are available and functional.

Continue glucose monitoring at least every 60 minutes and treat to prevent hyperglycemia.

Consider supplying increased oxygen (80% FiO₂) to reduce the incidence of wound infections and possibly PONV.

Administer ondansetron (4 mg intravenously) less than 2 hours before the end of surgery for patients at highest risk of PONV.

Use a standard sign-out routine to make certain all counts are correct and all specimens are properly labeled. Also summarize any issues or concerns pertinent to the specific patient's postoperative care. This may include the need for extended postoperative monitoring if any cardiac or respiratory events occurred during the procedure.

Remove the Foley catheter at the end of the procedure (if applicable).

Suggested Postoperative Guidelines

Recovery Area or Postanesthesia Care Unit

Continue patient warming with forced air in the recovery area or PACU if the patient is hypothermic. If shivering develops, intensify warming efforts and consider medication with meperidine or other drug.

Consider continuing 80% FiO₂ for 2 hours with a non-rebreather mask.

Continue IPCs or SCDs for DVT prophylaxis until discharge.

Do not extubate OSA patients until they are fully awake. Transfer them to a unit where their vital signs can be frequently monitored. Continue supplemental oxygen throughout hospitalization to maintain SpO₂ above 90%. Use a continuous positive airway pressure (CPAP) device in the hospital if a patient uses one at home. A 45-degree modified sitting position will improve ventilation. Use sedatives and pain medicine judiciously in OSA patients.

Continue close glucose monitoring in patients with diabetes and have insulin available for injection or infusion. Determine when and how patients should resume self-monitoring.

Manage fluids to maintain a urine output of 50 to 100 ml/hr.

Discontinue antibiotics within 24 hours unless there is a specific reason to continue.

Use a patient-controlled analgesia (PCA) pump for pain control with inpatients unless analgesia was provided with an epidural or nerve block.

If a patient develops PONV despite preventive efforts, do not repeat the same drug or drugs; order a drug that blocks a different receptor.

Begin ambulation on the evening of surgery.

Order incentive spirometry for all inpatients.

Make certain that printed postoperative instructions are given to the patient or a family member.

When indicated, begin chemoprophylaxis on the first postoperative day after checking the patient for any bleeding complications. Have the patient trained in the use of self-administered enoxaparin or fondaparinux, which should be continued for 7 to 10 days, especially with lower body procedures.

Postdischarge Recommendations

Remove drains when output drops below 30 ml/24 hr.

Minimize the use of liposuction compression garments to prevent permanent horizontal creases in the skin.

Instruct patients not to exercise or have sex for at least 3 weeks following major procedures.

Reinforce the idea that patients should avoid cigarette smoke. Repeat cotinine testing within 2 to 4 weeks when appropriate and document the results in the medical records.

Crisis Situations

Beyond the information presented in this chapter, plastic surgeons need to know how to manage life-threatening complications that may occur suddenly during surgery—malignant hyperthermia (MH) and local anesthetic systemic toxicity (LAST). These situations are quite rare but can develop in any surgical setting: the hospital, outpatient center, or office. The drugs, supplies, and treatment protocol needed to prevent death are discussed next. Successful recovery from MH or LAST requires rapid recognition of the problem, knowledge of what to do in the crisis, immediate action, and the availability of the treatment and monitoring equipment necessary. Neither condition can be studied with the types of clinical trials that underlie the safety recommendations described throughout this chapter, because treatment cannot ethically be withheld. Consequently, the treatment protocols described represent the current state of knowledge.

Malignant Hyperthermia

MH is a life-threatening, pharmacogenetic disorder of skeletal muscle metabolism triggered by volatile inhalation (gas) anesthetics and/or the depolarizing muscle relaxant succinylcholine. MH occurs only in people with a genetic trait that makes them susceptible, yet few people planning surgery would know they carry the trait for this inherited myopathy, which is detected by genetic testing or muscle biopsy. Consequently, every surgical patient should be presumed to be susceptible to MH. An episode of MH begins when a triggering agent disturbs calcium homeostasis. If not quickly diagnosed and treated, MH may lead to sudden cardiac arrest and death during or after general anesthesia with any of these agents:

- Succinylcholine
- Halothane
- Sevoflurane
- Desflurane
- Isoflurane
- Enflurane
- Methoxyflurane

A surgeon may not intend to use any of these agents, but plans may change, regardless of the type of facility where surgery is performed. For example, the use of succinylcholine may be needed in an emergency situation to establish an airway. Consequently, all procedures that require more than local anesthesia should be performed in an accredited facility with staff who know what to do if MH develops.

The incidence of MH is unknown, but the Malignant Hyperthermia Association of the United States (MHAUS) estimates that 1000 cases occur each year. This would mean that two or three MH episodes happen every day in the United States. In an MH episode, intracellular free calcium is released in striated skeletal muscle and sustained muscle contraction is activated. The rapid escalation of muscle metabolism increases oxygen consumption, produces excess carbon dioxide, and breaks down ATP (adenosine triphosphate), which stores the energy of muscle cells. As more energy is expended, more heat is produced. The cell membranes eventually collapse and high levels of potassium (K) and creatine kinase (CK) are released into the bloodstream.

MH develops without warning. Unfortunately, its signs and symptoms are inconsistent, may appear in a different order, and are not all present in every patient in crisis. Important signs of MH include unexplained tachycardia, a rise in expired carbon dioxide, hypercarbia, hypoxemia, generalized or masseter muscle rigidity, cardiac arrhythmias, metabolic acidosis, and hyperkalemia. A rise in body temperature often occurs late in the episode, as does rhabdomyolysis, which is usually identified by high serum levels of creatine kinase, excretion of myoglobin in the urine (myoglobinuria), and renal failure.

Because MH may escalate into a life-threatening crisis within minutes, all operating room personnel must be quick to recognize it and initiate treatment with dantrolene sodium, which directly relaxes skeletal muscle and reduces the release of calcium within muscle cells. MHAUS is the best single source of information on MH, its development, symptoms, diagnosis, and treatment, and surgeons should familiarize themselves with its excellent website at www.mhaus.org. MHAUS also maintains a hotline that is staffed 24 hours a day, 365 days a year to help with diagnosis and treatment of MH. The hotline will put callers in touch with an on-call anesthesiologist who specializes in MH crises and can advise operating room staff throughout the treatment process. A call to the hotline should be one of the first actions taken if MH is suspected.

MH Hotline: 1-800-644-9737
(1-800-MH-HYPER)
Outside the US: 001-315-464-7079

Surgeons should download the treatment instructions for MH from the MHAUS website (see p. 61) and also order these guidelines in larger format wall posters.

EMERGENCY THERAPY FOR MALIGNANT HYPERTHERMIA

DIAGNOSIS vs. ASSOCIATED PROBLEMS

Signs of MH:

- Increasing ETCO₂
- Trunk or total body rigidity
- Masseter spasm or trismus
- Tachycardia/tachypnea
- Mixed Respiratory and Metabolic Acidosis
- Increased temperature (may be late sign)
- Myoglobinuria

Sudden/Unexpected Cardiac

Arrest in Young Patients:

- Presume hyperkalemia and initiate treatment (see #6)
- Measure CK, myoglobin, ABGs, until normalized
- Consider dantrolene
- Usually secondary to occult myopathy (e.g., muscular dystrophy)
- Resuscitation may be difficult and prolonged

Trismus or Masseter Spasm with Succinylcholine

- Early sign of MH in many patients
- If limb muscle rigidity, begin treatment with dantrolene
- For emergent procedures, continue with non-triggering agents, evaluate and monitor the patient, and consider dantrolene treatment
- Follow CK and urine myoglobin for 36 hours.
- Check CK immediately and at 6 hour intervals until returning to normal. Observe for dark or cola colored urine. If present, liberalize fluid intake and test for myoglobin
- Observe in PACU or ICU for at least 12 hours

ACUTE PHASE TREATMENT

1 GET HELP. GET DANTROLENE – Notify Surgeon

- Discontinue volatile agents and succinylcholine.
- Hyperventilate with 100% oxygen at flows of 10 L/min. or more.
- Halt the procedure as soon as possible; if emergent, continue with non-triggering anesthetic technique.
- Don't waste time changing the circle system and CO₂ absorbant.

2 Dantrolene 2.5 mg/kg rapidly IV through large-bore IV, if possible

To convert kg to lbs for amount of dantrolene, give patients 1 mg/lb (2.5 mg/kg approximates 1 mg/lb).

- Dissolve the 20 mg in each vial with at least 60 ml sterile, preservative-free water for injection. Prewarming (not to exceed 39° C.) the sterile water may expedite solubilization of dantrolene. However, to date, there is no evidence that such warming improves clinical outcome.
- Repeat until signs of MH are reversed.
- Sometimes more than 10 mg/kg (up to 30 mg/kg) is necessary.

- Each 20 mg bottle has 3 gm mannitol for isotonicity. The pH of the solution is 9.

3 Bicarbonate for metabolic acidosis

- 1-2 mEq/kg if blood gas values are not yet available.

- **4 Cool** the patient with core temperature >39°C. Lavage open body cavities, stomach, bladder, or rectum. Apply ice to surface. Infuse cold saline intravenously. Stop cooling if temp. <38°C and falling to prevent drift < 36°C.

5 Dysrhythmias usually respond to treatment of acidosis and hyperkalemia.

- Use standard drug therapy except calcium channel blockers, which may cause hyperkalemia or cardiac arrest in the presence of dantrolene.

6 Hyperkalemia – Treat with hyperventilation, bicarbonate, glucose/insulin, calcium.

- Bicarbonate 1-2 mEq/kg IV.
- For **pediatric**, 0.1 units insulin/kg and 1 ml/kg 50% glucose or for **adult**, 10 units regular insulin IV and 50 ml 50% glucose.
- Calcium chloride 10 mg/kg or calcium gluconate 10-50 mg/kg for life-threatening hyperkalemia.
- Check glucose levels hourly.

7 Follow ETCO₂, electrolytes, blood gases, CK, core temperature, urine output and color, coagulation studies. If CK and/or K⁺ rise more than transiently or urine output falls to less than 0.5 ml/kg/hr, induce diuresis to >1 ml/kg/hr and give bicarbonate to alkalinize urine to prevent myoglobinuria-induced renal failure. (See D below)

- Venous blood gas (e.g., femoral vein) values may document hypermetabolism better than arterial values.
- Central venous or PA monitoring as needed and record minute ventilation.
- Place Foley catheter and monitor urine output.

POST ACUTE PHASE

- **1** Observe the patient in an ICU for at least 24 hours, due to the risk of recurrence.

- **2** Dantrolene 1 mg/kg q 4-6 hours or 0.25 mg/kg/hr by infusion for at least 24 hours. Further doses may be indicated.

- **3** Follow vitals and labs as above (see #7)

- Frequent ABG as per clinical signs
- CK every 8-12 hours; less often as the values trend downward

- **1** Follow urine myoglobin and institute therapy to prevent myoglobin precipitation in renal tubules and the subsequent development of Acute Renal Failure. CK levels above 10,000 IU/L is a presumptive sign of rhabdomyolysis and myoglobinuria. Follow standard intensive care therapy for acute rhabdomyolysis and myoglobinuria (urine output >2 ml/kg/hr by hydration and diuretics along with alkalization of urine with Na-bicarbonate infusion with careful attention to both urine and serum pH values).

- **2** Counsel the patient and family regarding MH and further precautions; refer them to MHAUS. Fill out and send in the Adverse Metabolic Reaction to Anesthesia (AMRA) form (www.mhreg.org) and send a letter to the patient and her/his physician. Refer patient to the nearest Biopsy Center for follow-up.

CAUTION:

This protocol may not apply to all patients; alter for specific needs.

Website
www.mhaus.org

Another valuable resource available from the MHAUS website is the description of the supplies needed for stocking the MH cart or kit that should be readily available at every surgical facility. The most important drugs needed for an MH kit are shown below.

Important Drugs for the MH Kit*

Dantrolene sodium for injection—at least 36 vials* (each to be diluted with 60 ml sterile water at time of use).

If surgery is performed on obese patients, 36 vials will be insufficient. For example, if a patient weighs 100 kg (220 pounds), 1000 mg of dantrolene may be needed (50 vials). The amount of sterile water for reconstitution and all other drug ingredients will also require adjustment.

Sterile water for injection USP (without a bacteriostatic agent) for reconstitution of dantrolene: Two 1000 ml bags.

Five sodium bicarbonate (8.4%): 50 ml syringes.

Two dextrose 50%: 50 ml vials.

Two calcium chloride (10%): 10 ml vials.

Four furosemide 40 mg ampules.

One regular insulin: 100 units/ml (refrigerated).

Lidocaine for injection: 100 mg/5 ml or 100 mg/10 ml in preloaded syringes.

*A complete list of required drugs, general equipment, monitoring equipment, nursing supplies, laboratory testing supplies, and forms required for an MH kit is available at <http://medical.mhaus.org/index.cfm/fuseaction/OnlineBrochures.Display/BrochurePK/B5DBDF12-20C3-4537-948C098DAB0777E3.cfm>.

Supplies for rapid patient cooling should also be readily available, such as a minimum of 3000 ml refrigerated saline solution and large and small plastic bags that can be filled with ice.

MH is rare, but all surgeons and anesthesiologists should be prepared to manage an MH crisis. Rescue from MH may take hours and requires the efforts of a large team. As an example, 3 or 4 people are needed to reconstitute Dantrolene for infusion. Early recognition and preparation is the key to successful treatment of MH. Having a protocol in place and all the many supplies available may make the difference in saving a patient's life or reducing the chance of long-term morbidity.

Local Anesthetic Systemic Toxicity (LAST) and Lipid Infusion

The use of local anesthetics and regional blocks is common among plastic surgeons, but knowledge of what to do if toxicity develops and leads to cardiovascular collapse is not. Although all types of local anesthetics are capable of reaching toxic lev-

els, the aminoamides, which are metabolized in the liver, seem to be more often implicated in toxicity of brain and heart tissue. The aminoamides include bupivacaine, ropivacaine, lidocaine, levobupivacaine, mepivacaine, prilocaine, and etidocaine. There are some indications that levobupivacaine and ropivacaine may be less likely to cause cardiac toxicity.

Detection of LAST

Successful treatment of LAST greatly depends on its prompt diagnosis. Toxicity is not always immediately evident after anesthetic injection and may take up to 60 minutes to manifest, especially if tumescent solutions are used. Intoxication may develop at any time when local anesthetic is delivered through a catheter. Signs of minor systemic toxicity are usually neurologic and may include perioral numbness, facial tingling, restlessness, confusion, muscle twitching, drowsiness, tinnitus, metallic taste, dizziness, and slurred speech. Major toxicity is accompanied by sudden loss of consciousness, tonic-clonic seizures, hypertension followed by progressive hypotension, tachycardia, ventricular arrhythmias, bradycardia or asystole, ventricular fibrillation, and cardiac arrest. The cardiovascular signs are not always preceded by neurologic signs, and cardiac arrest may be the first indication of LAST.

Treatment of LAST

Evidence indicates that the infusion of lipid emulsion (20% Intralipid) can effectively reverse anesthetic toxicity, whether the anesthetic is delivered locally or regionally. Every facility where local anesthetic is used in large doses should have a stocked Lipid Rescue Kit immediately available if a crisis arises. The same applies for cardiac monitors and supplies needed for Advanced Cardiac Life Support (ACLS), which should begin as soon as the need is recognized, before lipid rescue is attempted. Arrhythmias may be refractory to treatment and resuscitation measures will likely be needed for a prolonged period, perhaps 1 hour or more.

A Lipid Rescue Kit should be clearly marked and contain these supplies:

- 1000 ml of 20% Intralipid
- Intravenous tubing (for lipid infusion)
- 60 ml syringes and needles (for lipid bolus doses)
- A printed protocol

The protocol on pp. 64-65 was developed by the Association of Anaesthetists of Great Britain and Ireland (AAGBI) and is available at http://www.aagbi.org/publications/guidelines/docs/la_toxicity_2010.pdf.^{*} The American Society of Regional Anesthesia and Pain Medicine has a similar, though less detailed, protocol (www.rapm.org).

^{*}The British use a superscript negative number (ml.kg^{-1}) to denote what North Americans would refer to as “per” (ml/kg).

AAGBI Safety Guideline

Management of Severe Local Anaesthetic Toxicity

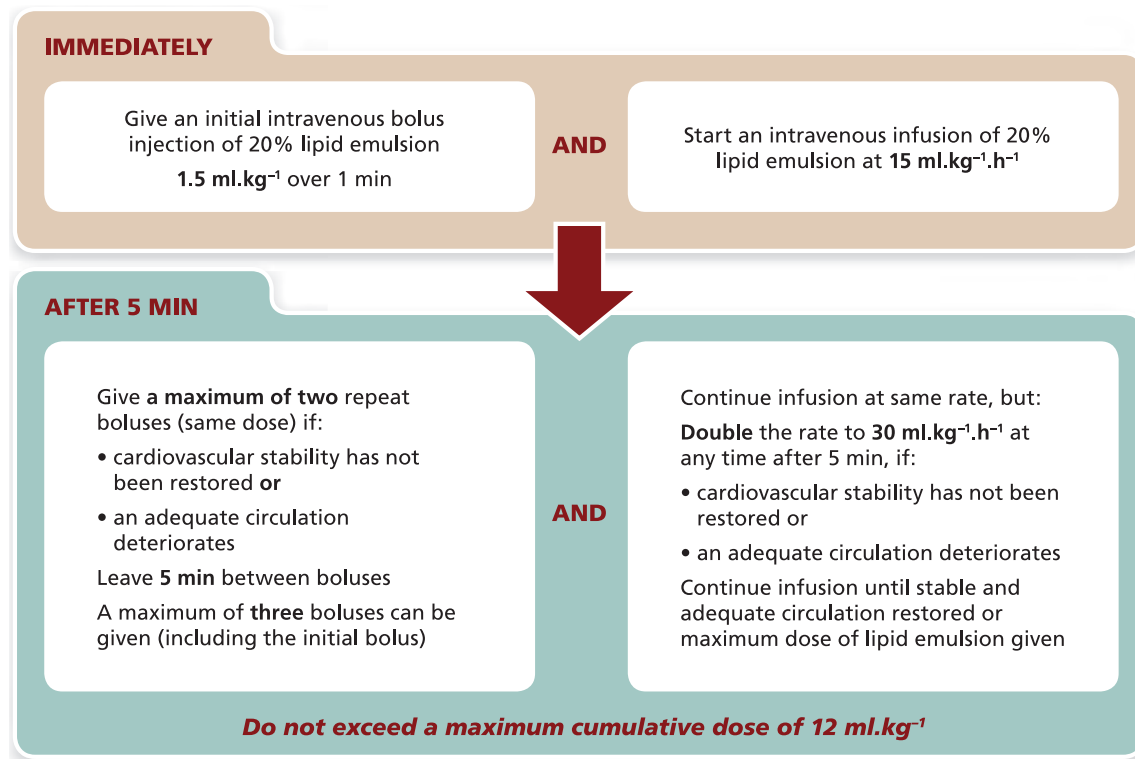

1 Recognition	Signs of severe toxicity: • Sudden alteration in mental status, severe agitation or loss of consciousness, with or without tonic-clonic convulsions • Cardiovascular collapse: sinus bradycardia, conduction blocks, asystole and ventricular tachyarrhythmias may all occur • Local anaesthetic (LA) toxicity may occur some time after an initial injection		
2 Immediate management	• Stop injecting the LA • Call for help • Maintain the airway and, if necessary, secure it with a tracheal tube • Give 100% oxygen and ensure adequate lung ventilation (hyperventilation may help by increasing plasma pH in the presence of metabolic acidosis) • Confirm or establish intravenous access • Control seizures: give a benzodiazepine, thiopental or propofol in small incremental doses • Assess cardiovascular status throughout • Consider drawing blood for analysis, but do not delay definitive treatment to do this		
3 Treatment	<table border="1"> <tr> <td data-bbox="539 880 961 1446"> IN CIRCULATORY ARREST • Start cardiopulmonary resuscitation (CPR) using standard protocols • Manage arrhythmias using the same protocols, recognising that arrhythmias may be very refractory to treatment • Consider the use of cardiopulmonary bypass if available GIVE INTRAVENOUS LIPID EMULSION (following the regimen overleaf) • Continue CPR throughout treatment with lipid emulsion • Recovery from LA-induced cardiac arrest may take >1 h • Propofol is not a suitable substitute for lipid emulsion • Lidocaine should not be used as an anti-arrhythmic therapy </td><td data-bbox="961 880 1367 1446"> WITHOUT CIRCULATORY ARREST Use conventional therapies to treat: • hypotension, • bradycardia, • tachyarrhythmia CONSIDER INTRAVENOUS LIPID EMULSION (following the regimen overleaf) • Propofol is not a suitable substitute for lipid emulsion • Lidocaine should not be used as an anti-arrhythmic therapy </td></tr> </table>	IN CIRCULATORY ARREST • Start cardiopulmonary resuscitation (CPR) using standard protocols • Manage arrhythmias using the same protocols, recognising that arrhythmias may be very refractory to treatment • Consider the use of cardiopulmonary bypass if available GIVE INTRAVENOUS LIPID EMULSION (following the regimen overleaf) • Continue CPR throughout treatment with lipid emulsion • Recovery from LA-induced cardiac arrest may take >1 h • Propofol is not a suitable substitute for lipid emulsion • Lidocaine should not be used as an anti-arrhythmic therapy	WITHOUT CIRCULATORY ARREST Use conventional therapies to treat: • hypotension, • bradycardia, • tachyarrhythmia CONSIDER INTRAVENOUS LIPID EMULSION (following the regimen overleaf) • Propofol is not a suitable substitute for lipid emulsion • Lidocaine should not be used as an anti-arrhythmic therapy
IN CIRCULATORY ARREST • Start cardiopulmonary resuscitation (CPR) using standard protocols • Manage arrhythmias using the same protocols, recognising that arrhythmias may be very refractory to treatment • Consider the use of cardiopulmonary bypass if available GIVE INTRAVENOUS LIPID EMULSION (following the regimen overleaf) • Continue CPR throughout treatment with lipid emulsion • Recovery from LA-induced cardiac arrest may take >1 h • Propofol is not a suitable substitute for lipid emulsion • Lidocaine should not be used as an anti-arrhythmic therapy	WITHOUT CIRCULATORY ARREST Use conventional therapies to treat: • hypotension, • bradycardia, • tachyarrhythmia CONSIDER INTRAVENOUS LIPID EMULSION (following the regimen overleaf) • Propofol is not a suitable substitute for lipid emulsion • Lidocaine should not be used as an anti-arrhythmic therapy		
4 Follow-up	• Arrange safe transfer to a clinical area with appropriate equipment and suitable staff until sustained recovery is achieved • Exclude pancreatitis by regular clinical review, including daily amylase or lipase assays for two days • Report cases as follows: - in the United Kingdom to the National Patient Safety Agency (via www.npsa.nhs.uk) - in the Republic of Ireland to the Irish Medicines Board (via www.imb.ie) If Lipid has been given, please also report its use to the international registry at www.lipidregistry.org. Details may also be posted at www.lipidrescue.org		

Your nearest bag of Lipid Emulsion is kept

This guideline is not a standard of medical care. The ultimate judgement with regard to a particular clinical procedure or treatment plan must be made by the clinician in the light of the clinical data presented and the diagnostic and treatment options available.

© The Association of Anaesthetists of Great Britain & Ireland 2010

An approximate dose regimen for a 70-kg patient would be as follows:

This AAGBI Safety Guideline was produced by a Working Party that comprised:
Grant Cave, Will Harrop-Griffiths (Chair), Martyn Harvey, Tim Meek, John Picard, Tim Short and Guy Weinberg.

This Safety Guideline is endorsed by the Australian and New Zealand College of Anaesthetists (ANZCA).

The timing of lipid infusion delivery is still being debated. It is probably unwise to wait until ACLS has been determined ineffective, because early treatment of LAST with lipid infusion can prevent cardiovascular collapse. However, only a small portion of patients will advance to life-threatening toxicity. The midpoint between the two extremes may be to start lipid rescue when LAST seems clinically severe and is progressing rapidly. Cardiac life support should continue throughout the lipid rescue treatment.

Additional Points to Remember

High doses of epinephrine can impede the effectiveness of lipid rescue. Low doses in the range of 1 $\mu\text{g}/\text{kg}$ can be safely used for hypotension.

Continue to monitor patients who had indicators of cardiac toxicity for at least 12 hours after they are stable. Cardiac depression can return after successful treatment.

Report LAST events and treatment at www.lipidrescue.org. If lipid emulsion is used, register the event at www.lipidregistry.org.

Concluding Thoughts

A culture of safety cannot emerge as long as there is a culture of blame and unwillingness to change behaviors and processes. Part of building a successful team requires overcoming cultural barriers that impede some members of the surgical team from speaking up because they are intimidated, are afraid of seeming foolish, or do not think the surgeon values their opinions. Every staff member in an operating room probably has something important to say about how safety practices could be improved, but nothing will change unless these ideas are shared among surgical team members.

According to AHRQ, the main component needed to improve patient safety is someone who will champion necessary changes. If a single surgeon seriously commits to the need for change in safety practices, others will follow this leadership when properly educated about the evidence behind the change. Thus frequent in-service training, effective reminder systems, and prominent, well-designed checklists are essential. Progress should be recognized. In addition, plastic surgeons must perform more thoughtful research to identify potential problems and solutions that will improve our safety processes and practices. We also need to do a better job of tracking outcomes.

Surgical patients have every reason to assume their safety will be protected and they will not be harmed. Adverse events are almost always a surprise to everyone involved in a procedure. The best way to prepare for them is to be proactive and take the ac-

tions necessary to prevent the error in the first place. Keeping up with the latest literature related to patient safety could be practically a full-time job, and most plastic surgeons are so busy that they rarely sample the literature of other medical specialties, such as anesthesiology, where much of the patient safety research is published. Even so, we have a responsibility to keep pace with evidence-based patient safety guidelines and protocols and turn them into actual practice.

CHAPTER 3

Sedation and Anesthesia for Aesthetic Surgery

DONALD W. BUCK II, THOMAS A. MUSTOE

According to the American Society of Plastic Surgeons (ASPS), more than 80% of all aesthetic surgery procedures are performed outside the hospital setting. As the number of office-based surgical procedures continues to rise exponentially, plastic surgeons have begun to embrace a less-invasive means for providing effective anesthesia: local anesthesia with sedation. There are two major states of sedation used for procedural anesthesia: (1) deep sedation (DS), or monitored anesthesia care (MAC), and (2) conscious sedation (CS). The success of both techniques has been well described in the literature, spanning numerous surgical and nonsurgical specialties, including plastic surgery, oral and maxillofacial surgery, otolaryngology, cardiology, gastroenterology, pulmonology, interventional radiology, and dermatology. A critical component of successful sedation is achieving effective local anesthesia, which we will emphasize in this chapter.

Conscious sedation is defined as an altered state of consciousness leading to a comfortable state of relaxation while maintaining airway patency and respiratory drive. During CS, the patient is capable of responding to verbal and physical stimuli. This is the hallmark difference between CS and DS techniques. During DS, the patient maintains airway patency and respiratory drive but is often unresponsive to stimuli.

Sedation techniques have many proven advantages over traditional general anesthetic techniques. In contradistinction to general anesthesia, patients under CS and DS are capable of generating respiratory drive and protecting their airway, thereby obviating the need for intubation. This fact alone prevents the development of airway complications such as pain, edema, injury, and pneumonia that are often associated with mechanical ventilation. In addition, although patients under general anesthesia are immobile and lack lower extremity muscle tone, patients under CS and DS maintain the ability to contract lower extremity musculature, thereby eliminating the venous stasis that can lead to deep venous thrombosis (DVT) and pulmonary embolus. This is especially true in CS patients, who are in a much lighter state of sedation, which allows them to shift their position throughout the procedure. It has been reported in the literature that the risk of DVT is up to threefold greater in patients undergoing general anesthesia compared with those receiving conscious sedation.

Other important advantages of sedation techniques include a lower incidence of postoperative nausea and vomiting and fewer unplanned hospital admissions, because inhalational anesthetics and/or high-dose narcotics are not used. In addition, post-procedure recovery is more rapid as a result of the short half-life of most sedative medications used in CS and DS techniques.

Although sedation techniques offer many advantages over general anesthesia, they are not without a few important disadvantages. Because patients are not entirely asleep, there is the risk that they will recall the procedure and the experience of pain

during the operation. Both can be avoided by carefully selecting and administering the appropriate balance of sedative medications and analgesics.

Deep Sedation/MAC Anesthesia

The mainstay of most deep sedation protocols is propofol. Propofol is an intravenous nonbarbiturate sedative that is most widely used as an induction agent for general anesthesia. Although the elimination half-life is 30 to 60 minutes, the observed duration of action is much shorter because of its rapid distribution into peripheral tissues such as muscle and fat. Therefore the clinical effects of propofol last approximately 2 to 3 minutes. This rapid onset and recovery make propofol an ideal medication for intravenous deep sedation. In DS techniques, propofol is often continuously infused at the lowest possible dose to maintain appropriate sedation depth.

Despite its rapid pharmacokinetic profile and the lower incidence of nausea and vomiting, patients under deep sedation with propofol can experience procedural recall if the level of sedation varies during surgery. Of even greater importance, patients can show great variability in their clinical response to administration of propofol, at times showing profound sedation even with the smallest doses, with a very rapid effect. This variability, coupled with its lack of reversibility, restricts propofol's utility in most *conscious sedation* protocols. In some states, propofol can only be administered by an anesthesiologist who maintains appropriate CME credits on its use. Because there is no reversal agent for propofol and the potential exists for respiratory depression, the person administering propofol must be trained in airway control and assisted ventilation. For these reasons, most advocate the assistance of an anesthesiologist or certified nurse anesthetist (CRNA) if DS is employed in the office setting. Hypotension related to systemic vasodilation is also a side effect but is not difficult to manage.

Conscious Sedation

The American Society of Anesthesiologists (ASA) advocates treating CS techniques as a combination of anesthesia and analgesia. In their consensus statement for nonanesthesiologists, they recommend targeting these factors individually with an appropriate combination of sedatives and narcotics. Commonly used sedatives include midazolam, diazepam, and ketamine. Commonly used narcotics include fentanyl and its derivatives. There have been numerous reports in the literature describing various combinations of these agents. Although ketamine has been used safely, and some practitioners have had extensive experience without problems, because of

its lack of reversibility and potential for respiratory depression, it is unclear whether its use should expand to office-based settings without the assistance of an anesthesiologist. By far the most common combination, and the one used exclusively at our institution is midazolam and fentanyl.

Midazolam is a benzodiazepine agonist with a rapid onset and recovery and causes very few cardiopulmonary effects. It is water soluble, resulting in very little venous irritation, and intravenous injection is painless. In addition, midazolam administration causes retrograde amnesia in a dose-responsive fashion, thereby limiting patient recall. Midazolam is also reversible; in the event of an overdose, flumazenil can be administered to reverse the benzodiazepine effects. However, benzodiazepines affect respiration much less than narcotics do, and the dose response is very graded, so reversibility has in practice never been required in our experience. Midazolam has been used successfully for CS in continuous and bolus dose fashion. The only absolute contraindication for the use of midazolam is in patients with benzodiazepine hypersensitivity or acute angle-closure glaucoma. Relative contraindications include pregnancy and the presence of significant cardiac and pulmonary diseases.

Fentanyl is a synthetic mu opioid receptor agonist. It is one of the strongest opioids available, with a potency 80-fold greater than morphine and 100-fold greater than heroin. It has a rapid onset and recovery, an acceptable side effect profile, and is reversible, making it the ideal analgesic for CS. There are many fentanyl analogs on the market today, including alfentanil (ultra-short acting: 5 to 10 minutes), sufentanil (5 to 10 times more potent than fentanyl), and remifentanil (shortest acting), but because of their very short action and their potency, they have not found wide usage in aesthetic surgery. Common side effects with all narcotics include constipation, somnolence, dizziness, anxiety, cardiopulmonary depression, and nausea and vomiting. These side effects can be reduced by limiting the total administered narcotic dose. Respiratory depression is the major side effect in practice, and it is important to note that benzodiazepines potentiate this effect. The peak onset is 6 to 12 minutes, so it is critically important to space the dosing with small increments to avoid overshoot in clinical effect. In the event of an overdose, naloxone can be administered, but in the cumulative clinical experience at Northwestern University, naloxone reversal has been necessary in less than 1 in 1000 cases. With increased attention to limiting the dose (usually 25 to 50 μg for local anesthetic injection, with cumulative doses for an entire procedure not to exceed 250 μg), and the short effective clinical half-life, the potential need for a reversing agent is reduced even more. The half-life of naloxone is much shorter than that of fentanyl. If a patient has received a significant dose of fentanyl, it may be necessary to readminister naloxone.

It cannot be overemphasized that the key to the CS technique and maintenance of the CS state is through the use of the described medications in small, incremental

doses that are properly spaced (every 5 minutes for benzodiazepines; slightly longer for fentanyl, depending on patient alertness and the level of sedation/analgesia). This allows appropriate titration of medications to limit or reduce the risk of side effects and maximize efficacy of sedation and patient comfort. Titration of medications is guided by close observation of the patient's vital signs, including respiratory rate, oxygen saturation, and overall state of alertness. An example of this technique is discussed next.

The Conscious Sedation Technique

After obtaining informed consent, and before the operation begins, patients receive three premedications: an antibiotic, an antiemetic, and an anxiolytic. As with most aesthetic surgery cases, patients receive an antistaphylococcal antibiotic as prophylaxis. At our institution we typically use 1 or 2 g of cefazolin in penicillin-sensitive patients and 900 mg of clindamycin in penicillin-allergic patients. Administration of an antibiotic is followed by an antiemetic; at our institution we administer 4 mg of ondansetron (Zofran) intravenously. Finally, patients are given intravenous diazepam (Valium) for anxiolysis. Diazepam is generally injected in incremental doses of 5 to 10 mg until adequate preoperative subjective relaxation is achieved. The appropriate state of preoperative relaxation is confirmed by slurred speech, a tendency to speak softly, and nystagmus. The observation of even slight nystagmus allows the physician to objectively monitor when an effective sedating dose of diazepam has been achieved. The most common dosing of diazepam is between 10 and 50 mg, but in patients with a history of diazepam usage or other neuroleptic drug use, much higher doses are occasionally used. The major problem with higher dose diazepam administration is the potential for prolonged postoperative drowsiness, which may extend the time to discharge. Most patients also receive between 0.1 and 0.2 mg of clonidine. Clonidine has been shown to improve sedation, stabilize vital signs, and decrease the amount of narcotic analgesic required as a result of its intrinsic analgesic and anxiolytic properties.

Once the patient is in the operating room, cardiac monitors, a pulse oximeter, and blood pressure cuffs are applied. One nurse or assistant is responsible for continuously monitoring patient status through these methods. This individual must have appropriate experience and background in continuous patient monitoring. In many cases this is a CRNA trained in airway management. The patient's status is reported to the surgeon in 5-minute increments. Any change among the measured parameters (vital signs, oxygen saturation, level of alertness, or blood pressure) is communicated to the surgeon. On the basis of these parameters, the patient receives 0.5 to 3 mg of incremental bolus midazolam for sedation and/or fentanyl in increments of 12.5 to 25 μg .

Local Anesthesia: A Critical Component of Sedation Anesthesia

As a result of the increasing number of office-based procedures and the subsequent increase in the use of sedation anesthesia, local anesthesia has become a critical adjunct to office-based surgical practice. We think that effective sedation and anesthesia in aesthetic surgery begins and ends with adequate local anesthesia. Thus we will discuss local anesthesia techniques in detail.

Commonly Used Local Anesthetic Agents

Agent	Class	Duration of Action (min)	Recommended Dosage Guidelines (mg/kg)	Maximum Total Dosage (mg)
Procaine (Novocain)	Ester	15-60	7.0	350-600
Lidocaine (Xylocaine)	Amide	30-60 120-360	Without epinephrine: 4.5 With epinephrine: 7.0	300
Mepivacaine (Carbocaine)	Amide	45-90	7.0	400
Bupivacaine (Marcaine)	Amide	120-240 180-420	Without epinephrine: 2.5 With epinephrine: 2.5-4.0	175 225-400

Plastic surgeons are extremely familiar with the available local anesthetics and basic infiltration techniques. The most commonly used compounds include the esters procaine, tetracaine, and chlorprocaine and the amides lidocaine, mepivacaine, bupivacaine, etidocaine, and prilocaine. A thorough knowledge of the pharmacokinetics of the commonly used agents is imperative to optimize anesthesia, analgesia, and patient comfort, while minimizing the risks associated with these agents.

Allergic reactions are rare and are more likely to occur with an ester compound. Toxicity usually results from an overdose. Systemic manifestations can include headaches, tinnitus, perioral paresthesias, restlessness, seizures, apnea, and cardiac depression. Surgeons should follow recommended guidelines regarding safe maximum dosages to reduce the risk of toxicity. The maximum dosage can often be extended by adding epinephrine to the anesthetic agent.

In 1987 Klein first described the tumescent technique, which involved infiltration of large volumes of dilute lidocaine with epinephrine into the local subcutaneous tissues to assist with suction lipectomy. During his seminal work, he discovered an important concept—the maximum dosage of lidocaine with epinephrine that could be safely injected extended well beyond the recommended guidelines of 7 mg/kg. In fact, he had safely used doses as high as 35 mg/kg without reaching toxic plasma levels. Since that report, a similar study by Ostad et al found that doses as high as 55 mg/kg can be used. Over the next several years it became increasingly clear that the tumescent technique offered significant perioperative advantages, including a reduction in surgical time, less potential for postoperative edema and hematoma, and improved postoperative pain control; furthermore, it eliminated the need for general anesthesia when paired with CS techniques.

This concept gained significant popularity over the following decade and has revolutionized local anesthesia technique. At this point the cumulative experience is in the millions of patients. In our practice we routinely approach the 35 mg/kg level of lidocaine, and in thousands of cases we have never encountered a hint of toxicity. One very useful safety feature of this CS protocol is that the antidote for early lidocaine toxicity (which is first manifested neurologically) is the administration of benzodiazepines, which have already been administered.

We employ the tumescent technique (or more accurately, flooding of the tissues with dilute local anesthetic, whether in the face, nose, breast, abdomen, or fat) in most of our aesthetic surgery cases using sedation anesthesia. Our goal is not to achieve turgidity of the tissues, but rather to achieve vasoconstriction, providing a bloodless field and truly effective local anesthesia.

Our dilute local anesthetic solution consists of lidocaine with epinephrine mixed in normal saline solution, which is sufficient to achieve anesthesia of fat. In our experience, 0.3% lidocaine is a sufficient concentration to achieve anesthesia for skin incisions, and approximately 0.1% lidocaine is sufficient to achieve anesthesia of breast tissue or muscle in sufficient volumes. Therefore our standard mix for skin incisions of the breast, abdomen, or face is 100 ml of 1% lidocaine, 1:100,000 epinephrine in 250 ml of normal saline solution, with 0.05% lidocaine for infiltration along abdominal fascia or in fat for liposuction. For breast reduction procedures under conscious sedation, 0.1% lidocaine is sufficient; however, to avoid skin complications, we limit the epinephrine concentration to 1:2,000,000. Depending on the specific procedure and anatomic location, an appropriate volume of solution is injected along the incision lines and into the regional soft tissues.

For example, during a breast augmentation procedure, after all incision lines have been adequately infiltrated, approximately 30 ml of dilute local solution is infiltrated directly into the subpectoral plane in the axillary portion of the breast to achieve effective regional breast anesthesia.

The table of injection techniques gives dilute anesthetic solutions for various aesthetic procedures.

Local Anesthetic Injection Techniques for Various Plastic Surgery Procedures

Procedure	Dilute Local Injection Technique
Face lift/brow lift	100 ml per side, along incision lines; 50-150 ml for submental region
Breast augmentation	100-150 ml for each breast, with dedicated 30 ml injected into subpectoral plane in axillary tail region
Mastopexy	250-500 ml for each breast, depending on breast size
Abdominoplasty	75-100 ml along all incision lines; 50-100 ml for abdominal fascia; remainder of solution for liposuction assistance where necessary

Outcomes and Safety

Our ability to provide less-invasive anesthesia and optimize patient comfort has advanced rapidly over the past 20 years. Despite these advances, we must maintain good clinical judgment and uphold superior standards in technical skills, surgical facilities, and patient safety. Office-based surgery can be performed safely and offers patients the highest degree of privacy and convenience, but surgeons must realize that the risk of serious injury or death exists. In fact, some published reports indicate that the risk of serious injury or death is tenfold higher for office-based procedures.

There is no doubt that the appeal of enhanced privacy, convenience, and comfort has substantially contributed to the number of patients seeking aesthetic surgery in the office setting. As with the truest of economic fundamentals, with this increase in demand, we have seen an unparalleled rise in the number of office-based procedures that are performed yearly.

To deliver optimal results in the safest environment, it is imperative that aesthetic surgeons adhere to strict guidelines set forth by governing bodies. For instance, the ASPS has published a series of guidelines to advise surgeons on appropriate safety measures for office-based practices. In addition to these specific guidelines, basic principles of ethical patient care should become the foundation of every aesthetic surgeon's practice. These include (1) performing office-based procedures in an accredited facility in accordance with policies set forth by the appropriate governing bodies, (2) only performing procedures for which one has been trained and is qualified to perform, (3) maintaining up-to-date, functioning equipment and appropriate facilities, and (4) applying the protocols necessary to create an environment in which the foremost concern is patient safety. All staff and personnel should be trained and certified to perform advanced cardiac life support (ACLS), efficiently manage emergencies, effectively stabilize patients, and appropriately transfer patients when necessary.

We have seen firsthand in our own practice the rising demand for sedation-based anesthesia and aesthetic surgery over the years. The well-publicized deaths from pulmonary embolus and respiratory complications have increased public awareness of the risks of general anesthesia. Over the past 15 years we have performed more than 4000 procedures employing the sedation and anesthesia techniques described in this chapter. The techniques have been widely used in our resident aesthetic clinic and by other plastic surgeons at Northwestern University.

As with all aspects of aesthetic surgery, achieving the optimal patient outcome and experience requires appropriate patient selection, operative planning, and realistic expectations. The delivery of appropriate sedation coupled with effective local anes-

thetia is a learned skill that requires the ability to pay significant attention to the level of sedation, stable vital signs, and oxygenation while focusing on the operation at hand. In practice, this means being alerted to changes in the patient's status by the monitoring nurse through 5-minute reports and maintaining a steady state of sedation by continued small increments of benzodiazepine administration.

We have used CS anesthesia for a wide range of aesthetic procedures, including suction lipectomy, abdominoplasty, breast surgery, rhytidectomy, blepharoplasty, and rhinoplasty. We have never had a patient develop deep venous thrombosis or a pulmonary embolism as a result of these techniques. Additionally, the risk of developing postoperative nausea and vomiting has nearly been eliminated with an effective balance of sedation, narcotic, and antiemetic prophylaxis. As a result, the incidence of unplanned hospital admission is extremely rare.

Key Observations

During our experience with CS, we have made several key observations that are important for surgeons employing CS techniques.

Patient Selection

1. The use of CS should be avoided in patients who are extremely anxious and have an absolute desire to be "out," with a stated very low pain tolerance. These patients may require large amounts of sedation, which prolongs the recovery and increases the risk for nausea and vomiting. However, with experience, and for easier procedures (such as rhinoplasty), some of these patients can still do very well with sedation.
2. For patients with any significant history of coronary artery disease, arrhythmias, or significant pulmonary problems, their procedure should be performed under MAC or DS with the assistance of an anesthesiologist to optimize patient safety.
3. Patients with a significant history of depression, bipolar disorder, or other mental illness may have unpredictable responses to sedation and should be considered for MAC.
4. Patients who take several neuroleptic drugs may be difficult to sedate, and caution should be used.

Procedural Considerations

1. Essentially any aesthetic procedure is applicable (including harvesting costal cartilage) if good local anesthesia can be achieved.
2. Patients can get restless after 4 hours; therefore we avoid using CS in procedures that last longer than 4½ to 5 hours.
3. For long procedures with significant fluid infiltration, insertion of a Foley catheter after the patient is sedated can be very useful.
4. Local infiltration, for liposuction for instance, with very dilute (0.05% xylocaine) can take 15 to 30 minutes for maximal effect.

5. Planning a procedure to minimize the number of separate times that local anesthetic is infiltrated eases the procedure. For instance, when doing a combination breast augmentation and abdominoplasty, we infiltrate both surgical fields completely at the beginning of the procedure when the patient is usually most deeply sedated. This enables the local anesthetic sufficient time to take full effect in both fields, while subjecting the patient to only one period of injections, significantly easing the procedure, and speeding it up.

Concluding Thoughts

As the number of office-based procedures and the demand for more convenient and safer anesthesia continue to rise exponentially, plastic surgeons must become comfortable with the techniques of sedation anesthesia to stay competitive with their colleagues. Sedation techniques can be applied for the majority of aesthetic procedures, so long as these procedures are performed in an accredited facility, with strict adherence to the appropriate standards and guidelines, with a particular focus on maintaining maximal patient safety.

Clinical Caveats

Sedation anesthesia results in less risk for deep venous thrombosis, pulmonary embolism, and postoperative nausea and vomiting.

The major distinction between deep sedation and conscious sedation is the patient's ability to respond to external stimuli.

Sedation anesthesia should be performed in accredited facilities by surgeons and personnel who are trained in medication administration and able to provide airway assistance if necessary.

The conscious sedation state can be maintained by careful titration of medications and administration in small, incremental bolus doses.

Appropriate local anesthesia is paramount to effective conscious sedation.

Office-based surgery can be performed safely, so long as surgeons adhere to the standards and guidelines set forth by appropriate governing bodies, with the primary focus on patient safety.

CHAPTER 4

Facial Aesthetic Surgery in Skin of Color

JULIUS W. FEW

According to 2008 statistics from the American Society for Aesthetic Plastic Surgery (ASAPS), persons of color represent the fastest-growing group of consumers in elective aesthetic medicine. With the increasing availability of information and awareness of the latest innovations, patients' expectations are high, and the need is clear for interventions that are individualized to the specific needs of ethnic patients.

Skin of color has more advantages than disadvantages when it comes to the aging process because of its inherent protection against actinic damage and its sebaceous nature and suppleness. Thus the types of interventions requested and the specific indications differ from those of patients with lighter skin. In addition, patients of color tend to present later in life than those with light skin.

In general, darker-pigmented skin has an increased epidermal melanin content and large, singly dispersed melanosomes within melanocytes. Melanosomes are distributed throughout the epidermis in darker skin, whereas in lighter skin they are limited to the basal and lower malpighian layer of the epidermis. Black/brown skin is thicker and the dermis more compact than white skin. Fibroblasts are large and numerous, and thus there is a significant turnover of collagen in dark skin. These findings may help to explain why skin of color is at an increased risk of adverse scarring with epidermal or dermal trauma.

Treatment Considerations for Skin of Color

The primary focus in treating skin of color relies on several major considerations. When treating the skin of ethnic patients, the surgeon must consider the presence and/or prevention of postinflammatory hyperpigmentation and hypertrophic/keloid scar tendencies. In general, there are a variety of surgical and nonsurgical options to help avoid these unwanted events. Excess tension, inflammation, and a genetic predisposition appear to play the major part in hypertrophic or keloid scar formation. As with any approach, surgical or nonsurgical, it is vital to neutralize all possible variables in an effort to avoid complications.

In some instances, the very nature of the treatment is keloidogenic. Face lifts and skin resurfacing are by their very nature keloid promoting in at-risk patients because of skin tension and inflammation, respectively. I have found that nonabsorbable su-

ture material is less reactive in at-risk skin types, thereby limiting local tissue inflammation. Nonabsorbable suture material can be removed subsequently, eliminating the potential offending agent. The surgeon must understand the fine balance between allowing the suture to control tension and the need to limit a reactive substrate.

If hyperpigmentation exists in an area in which cosmetic enhancement is planned, one should consider treating this before a procedure is performed. This is particularly applicable preceding injections of fillers or *botulinum* toxin. Regardless of skin tone, sunscreen protection is vital, especially with preexisting postinflammatory hyperpigmentation. For existing hyperpigmentation, I typically begin with a solution of 4% hydroquinone, 0.05% tretinoin, and 0.01% fluocinolone, which the patient applies nightly for 2 to 6 weeks before a planned surgery. Skin-bleaching therapy is resumed 1 week after the procedure. As with all forms of medicine, prevention is the key to a successful outcome.

INDICATIONS AND TREATMENT MODALITIES

The following discussion provides a general framework for the treatment of patients of color but is by no means an exhaustive list of treatment options for these patients.

Periorbital Rejuvenation

Most of the literature on facial aesthetics reflects white ideals, which runs the risk, if taken too literally, of conflicting with the desires of patients with other cultural ideals. However, there are goals that remain consistent, regardless of the patient's race, ethnicity, or sex.

The surgeon must strive for an approach that will restore and enhance appearance in the most natural way possible, without distortion of function. Most elective patients are not trying to assume the appearance of another person, but rather to feel that their outward aspect conveys a message consistent with their inner feelings. The most common comments heard in consultation for eyelid rejuvenation are a desire to “not look tired,” or “not look sad.” The endpoint sought by most patients is: “I want to look refreshed.”

Pertinent Anatomy

According to our study published in 2006, approximately 40% of African American women fear losing their ethnic identity if they undergo blepharoplasty, which emphasizes the importance of sensitivity to this issue. In studying the faces of patients of African descent, I have found a strong association with Asian features, especially with regard to the lateral canthus of the eye. When questioned, patients of color felt their eyes shared canthal and upper eyelid characteristics with those of Asian ancestry, although they clearly did not want to change their own ethnic character. In general, when questioned, patients in this group are not pursuing a younger look, or a change in ethnic characteristics, but rather a less-tired look.

The split-face image above demonstrates the composite nature of facial aging in an African American woman: the left side shows the patient 17 years before and the right side just before rejuvenation surgery. As Flowers and others taught us, the periorbital aging process begins at the forehead/brow region. The process begins with forehead redundancy and flattening of the brow apex. Crowding of the lateral and central upper eyelid occurs as the brow migrates inferiorly. The upper lid often loses its septal support, leading to brow prolapse and an exacerbation of upper eyelid fullness and congestion. The lateral canthal complex then migrates inferiorly, loosening the lower eyelid sling. The lower lid then takes on an elongated appearance, and tear troughs and nasojugal sulci develop. This is followed by ptosis of the midface and deepening of the nasolabial sulcus. Finally, jowls form. Reviewing the patient's more youthful photos is vital in planning periorbital surgery.

Preoperative Planning

A successful outcome depends on a successful surgical plan. When selecting the overall approach, surgeons must realize that patients of color are looking for significant improvement but fear overcorrection more than white patients do, according to our research. Past photos are reviewed primarily to assess normal canthal and periorbital landmarks for surgical planning. In general, I prefer to perform canthopexy liberally to restore canthal tilt, preserve the majority of the upper eyelid orbicularis as

an autologous graft, and place the upper blepharoplasty closer to the ciliary margin than in a typical white eyelid (taking care to measure the exact height of the tarsal cartilage). If supratarsal malposition is found in the upper eyelid, the surgeon and patient discuss ptosis correction versus three-point fixation of the supratarsal crease. Ptosis surgery is recommended in patients adversely affected by the condition and/or those desiring restoration to a more youthful appearance. Regardless of race or ethnicity, it is vital to beware of patients with dry-eye syndrome, because ptosis correction will exacerbate these symptoms.

For patients of African heritage, I find that canthal ptosis with aging occurs at a faster rate than in white patients. This finding is based on controlled photo files analyzed with high-resolution photography and computer evaluation of the canthal angle in more than 500 subjects. Although the lateral canthus starts higher than the medial canthus in a youthful patient of color, the drop over time is relatively dramatic. The surgeon may be deceived to find the medial and lateral canthal points equal, a common finding in the white population, and mistakenly leave this malposition untreated while other periorbital concerns are addressed. This omission leaves the patient with an incomplete correction and subjective dissatisfaction.

Brow ptosis in persons of color occurs to a lesser extent and at a much later age than in white patients. Despite great advances with light-based treatments, laser therapy to the lower eyelid in skin of color remains a challenge. Given the rare finding of excessive lower eyelid skin after treatment of redundant deeper tissue, immediate sub-ciliary skin-pinch excision is preferred. The removal of skin in this location is very effective and safe, typically leaving no signs of surgical intervention.

I have found that 6-0 Prolene suture in skin of color leaves no identifiable marks. This approach has even been used in patients with a known history of keloid formation in other parts of the body.

Once the surgical plan has been defined, there are techniques that are common to patients of all ethnic backgrounds. In particular, this involves (1) supporting the brow-forehead aesthetic unit to provide the scaffold for successful periorbital rejuvenation and (2) assessing risk factors in the rejuvenation plan.

There are considerations unique to patients of color, and these require a modified approach to achieve the desired outcome. Because most of these patients do not have significant signs of aging in the forehead region until much later in life, the focus is typically set on balancing the brow position and providing support for the planned eyelid repositioning. I have found that internal browpexy is ideal for these patients, limiting the scar to the supratarsal area. The upper eyelid becomes deflated over time, making preservation and restoration the most important variables. Fat excision is often limited to the nasal upper eyelid fat compartment. One must be very conservative with fat excision in the more lateral compartments. The upper eyelid is an ideal access point for lateral reticular release and lateral canthopexy.

Given the unique challenges of pigmented skin and visible scarring, I have found it ideal to attempt to keep visible scars within the confines of the lateral canthal point. For this reason, I developed the *transconjunctival deep plane midface lift*. This is a technique that provides primary access to the lower lid and midface through the transconjunctival approach and eliminates the need for traditional skin muscle flap surgery and the accompanying scar. In addition, the approach leaves the orbicularis muscle undisturbed, minimizing the risk of eyelid malposition from muscle contracture or paralysis. With the orbitomalar ligament divided, the midface is readily available and amenable to suture fixation after elevation. This technique can often replace or eliminate the need for more traditional face-lift approaches.

Because there are often few rhytids visible on the skin of patients of color, deep autologous fat injection and/or grafting is ideal for malar restoration and tear-trough augmentation. I prefer the lateral ala and oral commissure as access points for fat injection. The ideal fat graft for skin of color is the dermal or septal fat graft for tear-trough and direct malar augmentation. Patients are advised that the implanted autologous tissue will initially feel hard to the touch and undergo maturation and softening over 6 to 12 weeks. Although a patient of African descent may wish to preserve a natural appearance, it is important to slightly overcorrect, anticipating the post-operative relapse and “settling” of the surgical manipulation. I always use nonabsorbable suture to limit the risk of hyperpigmentation and/or the suture reaction seen with absorbable material. The sutures are removed at 4 to 7 days, thus limiting the potential for a suture reaction.

It is not possible to cover every nuance of periorbital rejuvenation in patients of color, but I will provide some illustrative examples of technical approaches to the area. I will describe the treatment approach and rationale in two African American women to demonstrate the algorithm for both primary and secondary rejuvenation.

Preoperative

Long-term postoperative result

This woman presented in her late fifties wanting to look “less tired.” The split image emphasizes the changes that have occurred; the appropriate location for her lateral canthus relative to the medial canthus can be seen. It is important to recognize her asymmetry before the procedure. In particular, her right brow is lower and flatter than the contralateral side, creating a more hooded appearance to the right upper eyelid. She has forehead rhytids, but they are largely reactive and dynamic, involuntarily responding to brow and eyelid ptosis. With transpalpebral brow correction, the forehead assumes a more aesthetic position, making direct forehead rhytidectomy unnecessary. With these findings, I prefer to approach this indication with peri-orbital access only.

In addition, I address upper eyelid excess while preserving the underlying orbicularis and conservative resection of the nasal fat pad. Because her lower lid distraction is less than 6 mm, a canthopexy is planned with a lateral retinacular release. Because the patient has significant tear-trough deformity, septal fat prolapse, and submalar depression exacerbating midface ptosis, a transconjunctival deep plane midface lift will be done. A tear-trough fat graft will soften the sulcus. The procedure can be done under monitored anesthesia care (MAC) or general anesthesia, depending on surgeon and patient preference.

Markings

The supratarsal crease is marked with the patient awake and in the upright position. The desired apex of the brow is marked at the level of the lateral limbus of the iris, marking preoperative asymmetry. The redundant skin of the upper eyelid is marked, with the brow in the desired corrected position. Care is taken to not take the cephalic limb of the upper lid excision beyond the midpoint of the area between the supratarsal crease and inferior edge of the natural brow.

Operative Technique

The procedure begins with the patient supine. After the appropriate marks have been made, tetracaine ophthalmic drops are placed, followed by lubrication and protective, evaginated corneal shields. A solution of 1% lidocaine with epinephrine 1:100,000 is injected in the field, regardless of the level of anesthesia. The surgical incision begins with an upper blepharoplasty; excess upper eyelid skin is removed while preserving the underlying muscle.

The muscle is then divided at the level of the supratarsal crease, preserving the underlying septal extension. The muscle is elevated in a cephalad direction, using insulated needle tip cautery. Care is taken to identify and preserve the supraorbital neurovascular bundle. Dissection on the supraorbital rim is done deep to the subor-

bicularis fat pad but superficial to the periosteum. The lateral brow retaining ligaments are separated, allowing release of the caudal 3 cm of the forehead from the brow. The surgeon then conservatively resects nasal fat excess using the needle tip cautery. Release of the lateral retinaculum, as described by Jelks (see p. 94), is done through the upper lateral eyelid exposure. The lateral 1.5 to 2 cm of periorbital orbicularis is elevated off the periosteum, allowing exposure of the lateral retinaculum and upper and lower lateral septal fat compartments. Selective release of the retinaculum without lysing the canthal tendon can be done through this approach under direct vision.

The surgeon then turns to the transconjunctival approach (see p. 92). A conjunctival 5-0 silk traction suture is placed 8 to 10 mm from the inferior ciliary margin. The transconjunctival incision is made above the traction suture and a preseptal exposure is developed deep to the orbicularis muscle. The arcus marginalis and orbitomalar ligament are identified and preserved. The orbital malar ligament is divided with needle tip cautery, preserving the arcus marginalis and periosteum. A preperiosteal dissection is carried down to the desired level of correction, keeping all fat and soft tissue off the periosteum. One can readily reach the level of the ala while carefully identifying and protecting the infraorbital neurovascular bundle. Using the deep orbicularis to arcus marginalis, one- or two-point fixation can be performed through the transconjunctival exposure with a 4-0 Vicryl or PDS suture on a small tapered needle. Care must be taken to avoid incorporating capsulopalpebral fascia or conjunctiva in the closure, since this could lead to lid malposition. One- or two-point suture fixation, deep orbicularis to periosteum, is performed through the lateral aspect of the upper blepharoplasty exposure.

Suture fixation of the lateral canthus to the interior of the lateral orbit periosteum

After securing the lateral aspect of the midface while taking care to preserve the zygomaticofacial nerve located at the malar eminence, the surgeon performs the lateral canthopexy. I prefer 4-0 Mersilene or braided ophthalmic nylon, double-armed, to plicate the lateral canthal tendon to the interior aspect of the superolateral periosteum. The knot is carefully buried. Attention is then turned to the browpexy.

Sagittal view: Layers of the upper eyelid

Layers of the upper eyelid to gain access to the brow for internal browpexy

The apex is identified and the inferiormost aspect of the brow margin is transposed to the deep surface of the orbicularis. The deep orbicularis is then anchored to the periosteum of the frontal process, typically 1.5 to 2 cm above the supraorbital rim using a 5-0 Vicryl suture. The surgeon must be careful not to overcorrect, because the brow tends to migrate superiorly over time with thorough brow release.

Finally, the upper blepharoplasty incision is closed with a running 6-0 Prolene suture. Any redundant lower eyelid skin can be removed using a skin-pinch excision, preserving the underlying orbicularis.

Postoperative Care

A Steri-Strip bolster dressing is placed to support and reinforce the superolateral lift of the midface-cheek unit. The conjunctival incision is not closed. Ophthalmic lubrication is not instilled for the first 48 hours after surgery to avoid a granulomatous reaction. The patient can place cool compresses over the eyes for the first 36 to 48 hours and liberal applications of an ophthalmic steroidal agent if significant chemosis appears (a rare finding).

Results

This patient illustrates the importance of having a well-laid plan and understanding what the patient really desires. This woman had undergone a four-lid blepharoplasty at another clinic more than a year earlier and was not pleased with her result, which she felt made her look “tired” and “unhappy.” She had objective signs of uncorrected canthal ptosis and lower lateral eyelid retraction, creating a gapping at the lateral aspect of the eye and increased scleral show. Had the previous surgeon looked at her more youthful photos, he or she would have appreciated the significance of her canthal ptosis and subsequent loosening of the lower eyelid mechanism. The inferior lateral cant of the eye makes her look angry. Given these findings, I felt that revision upper and lower blepharoplasties would be appropriate, with a transconjunctival deep plane midface lift. The midface lift is intended to recruit skin and soft tissue to the correct lower lid retraction and preserve an appropriate correction to the lateral canthus. In addition, the patient required a lateral reticular release with canthopexy, as previously described, to achieve harmony in the periorbital region. As the 3-year follow-up images show, this patient was able to achieve significant, persistent correction. Note the paucity of visible scar formation despite the revisionary nature of the intervention.

Patients of color are particularly well suited for autologous fat injection to the midface and tear trough, primarily because of the robust nature of the overlying skin and soft tissue. There are a variety of techniques for preparing and injecting the fat, but I have found tumescent aspiration with concentrated injection to work well. I do not advocate centrifugation; I simply use a sterile nonstick gauze pad or simple gravity filtration. The fat is then injected through concealed injection ports, such as the oral commissure or nasal ala. Slight overcorrection is done to offset the average take of 75%. I do not place sutures at the injection sites for closure because of the increased risk of prolonged or chronic suture tract marks.

Nonsurgical Periorbital Rejuvenation

In previous publications I have shown the safety and efficacy of using hyaluronic acid filler in facial soft tissue and skin restoration in skin of color. There has been no reported difference in adverse effects or complications with such synthetic fillers. I find that it is better to inject the filler in the deeper dermis, with as few points of injection trauma as possible. In addition, neurotoxin injection enhances the benefit. With injection of a neurotoxin initially, one can simulate a brow lift and correction of lateral brow hooding and crow's-feet. In patients with prolapse of the lower eyelid septal fat and a prominent tear trough, hyaluronic acid can be injected to correct the defect and deemphasize the prominence of the prolapsed fat. In addition, significant harmony can be achieved in the lid-cheek junction. The overlying skin tends to be thicker and is more forgiving of contour irregularities. I prefer to inject the glabella and forehead, preserving the caudal 1.5 cm of the frontalis overlying the brow apex, and injecting the crow's-feet area 1 cm away from the orbit. The exact dose varies, but I often supplement the above with 2 to 3 units injected directly into the superior border of the brow apex.

In a secondary procedure, the brow and tear trough can be injected with hyaluronic acid filler; this is an off-label indication. There are a variety of hyaluronic products that can achieve similar results, and it is ultimately up to the user to find the most appropriate option. I recommend using serial injection, placing the product on the periosteum laterally. As one progresses medially on the tear trough, the injections become more superficial while remaining submuscular. The nasojugal fold is the most superficial and requires great caution to prevent hematoma and/or a Tyndall effect. Care must be exercised so that the product is not deposited in the septum or the malar fat pad, because this can cause prolonged edema and will be counterproductive. A useful strategy is to inject 2 to 3 mm below the obvious tear trough and massage the area to mold the end result, thus almost guaranteeing that the product is not placed into or under the orbital septum. Linear threading is placed more nasally to avoid visible lumps and bumps.

Care is taken to not overcorrect. Patients are made aware of the option to do a secondary injection 2 weeks later, if needed. This is much better than having to use hyaluronidase to break down too much product. Secondly, hyaluronic acid filler can be injected to restore and lift the lateral brow and reinforce the brow apex. This injection technique requires deep injection and care to avoid the supraorbital neurovascular junction. Typically, I do not exceed 0.2 to 0.3 ml of product. I have found that filler in this area will consistently last more than 12 or more months, and I have seen patients with persistence beyond 24 months. This provides a great "trial run"

for a patient who is uncertain about the degree of correction desired or who wishes to avoid surgery at all costs. These options can also be used in a patient wanting only segmental correction, such as limiting the correction to just the brow and upper eyelids and using filler and *botulinum* toxin for the lower eyelid and cheek. Fillers provide an amazing option for correction in patients of color, providing a great deal of forgiveness and user friendliness for the surgeon.

Although the result is not surgical, one can see this patient's enhanced appearance following hyaluronic acid injection to the tear trough. The longevity of this filler is typically more than 12 months and in some cases more than 2 years because of the relative lack of tissue movement in the tear trough and brow. In addition, the injections involve minimal downtime.

Avoiding Problems

There are several advantages to treating the skin of patients of color. The overlying skin is often more robust and shows fewer rhytids over time. This means that surgical intervention will focus on deeper tissue changes, in particular restoration of ptotic tissue and lost soft tissue volume. As already noted, a common and avoidable omission is failure to use past patient photos, which can provide a roadmap to success. Youthful photos also aid in appropriate planning for positioning of the lateral canthal mechanism. Failure to reposition the lateral canthus will not only result in a poor cosmetic outcome, but will also place the patient at increased risk for lid malposition. It is important to plan the use of soft tissue fillers in these patients, either nonpermanent products or autologous fat.

The transconjunctival deep plane midface lift allows preservation of the orbicularis function while providing direct access to the ptotic cheek tissue and a mechanism for restoration of a visible tear trough. To avoid difficulty with this procedure, I recommend using an insulated surgical system made up of insulated retractors and an insulated needle tip cautery. In addition, the use of a fine, double-armed skin hook facilitates holding the deep midfacial tissue for suture placement. I recommend working from medial/nasal to lateral for suture fixation. The canthopexy should follow the midfacial suspension, but the canthopexy should not be expected to support the midface alone. Conservative skin removal is recommended to avoid widened scars or visible extensions.

Perception is reality. This is extremely important in aesthetic surgery, but it is especially so in patients of African heritage, given their culturally specific ideals of beauty. I prefer to meet with the patient at least twice; the focus of our discussion is on the patient's desired outcome. I make the patient aware that I will undercorrect rather than overcorrect, allowing for later modification as needed. This places the patient in the copilot seat and limits the potential for a later perception of failure. When there is doubt about the patient's long-range outcome goals, a temporary option such as fillers and neurotoxins may be used.

Rhinoplasty

Nasal aesthetic surgery in people of color is very clinically and culturally specific. Despite past attempts to compare the noses of white patients and patients of color, the aesthetic goals are very different for each. In addition, the underlying structures differ from those of white patients. Defining points such as alar width, tip fullness, and radix height are inherently distinct in different racial/ethnic groups. If one looks at individuals who personify beauty in the African, Latin, or Asian cultures, the norms for whites do not fit. Adding to the complexity, there is no one universal African, Latin, or Asian nose; there are multiple ideals within ethnic groups and multiple cultures. There have been unfortunate examples in the popular media demonstrating how inappropriate attempts at changing one's ethnic character to another can be; the results are always obvious and unnatural.

Although much can be gleaned from past teachings, there are limitations and pitfalls to the unswerving use of past approaches. In particular, I am not trying to "correct" or "gentrify" a patient's nose, but rather to enhance the appearance and bring it closer to a given ethnic/familial definition of beauty and balance. The following discussion represents my personal approach to ethnic rhinoplasty and will focus on useful concepts that can be molded to an individual practice.

Preoperative Planning

In general, I use the patient's family photos as a useful guide to the individual's aesthetic goals. This is extremely useful in patient consultation and in defining the desired end result. Unfortunately, present-day virtual simulation is not accurate enough to predict an ethnic patient's end result because of the intrinsic variability of defining points. Of the patients referred to my practice who have undergone surgery elsewhere, more than 50% of the cases involved the use of morphing software that the patients perceived as an implied guarantee. Occasionally I see patients who wish to completely change their ethnic identity—to assume the characteristics of another racial identity. I advise surgeons to employ extreme caution in this very small and dangerous subset of patients, because ultimately they will be extremely difficult to satisfy.

Preoperative

1 week postoperatively

2 years postoperatively

Although I prefer to produce a slightly undercorrected result, at the time of surgery the result must look slightly overdone to make up for the tendency of the skin envelope to swell significantly and the loss of tip support during the recovery period. This woman presented with severe lack of nasal tip support, to the point of complete collapse when she smiled. She did not want a drastic change, but to have a nose that looked more like her mother's.

An open-tip primary rhinoplasty was planned, beginning with a cephalic trim leaving 7 mm of lower lateral cartilage. The dorsal hump was reduced under direct vision, with a formal septoplasty for correction of an obstructing septal deviation to the left and harvest of donor cartilage. The nasal tip was then augmented with a columellar strut and placement of dome sutures. The alar flaring was managed with an internal diamond excision, as shown. Finally, the proximal nasal base was narrowed with a low-to-low nasal sidewall fracture. The progressive change in the preoperative and postoperative photos is shown on p. 101.

I prefer autologous tissue to alloplastic material in every case, but there are instances in which the donor supply is limited and/or the patient does not accept the risk of donor harvest. In these cases, it is vital to get complete soft tissue, beyond skin alone, to allow for long-term tissue integration and limitation of extrusion. Unfortunately, septal donor material is often limited if an extensive augmentation is planned. In general, I prefer to use auricular and costal cartilage, respectively, if available. If a patient is keloid prone, I will preferentially use alloplastic material rather than risk the development of ear or chest keloids. In patients with poorly controlled acne, I defer alloplastic implantation until the acne is under control and appropriate prophylactic treatment has been done.

In a patient of color who is uncertain about the idea of surgery or the end result, hyaluronic acid filler injection, used with caution as an off-label indication, can be a powerful tool. This is useful not only for demonstration purposes but also offers a reasonably long-term solution, typically more than 12 months, and favors the thicker skin envelope found in patients of color. This is an advanced application that requires significant understanding of the vascular anatomy to avoid inadvertent intravascular injection. A prime advantage is the ability to use hyaluronidase injection in patients who wish to remove the enhancement, typically providing complete resolution in 24 hours or less.

Before surgery, patients are made aware of the typical use of steroid injections during postoperative recovery. Patients are typically considered for their first injection of triamcinolone at 6 weeks after surgery. The injection is always placed deep to the dermis with a microdroplet injection technique in the tip. A 27-gauge or smaller needle is used and a concentration of 40 mg/ml is used so that the medication can be diluted 50%, with 1% lidocaine. A typical injection for my African American patients is 5 to 10 mg; I do not defat the dermis at the time of surgery. I then consider an additional injection of a steroidal agent at 3, 6, and 12 months after surgery.

At all costs, I avoid visible scar placement. The use of Weir alar excisions can typically be avoided by using the internal alar excision, completely hiding the future scar, as demonstrated on p. 101. Most primary cases are done via an open approach, using the natural recess located in the slightly hyperpigmented area at the columellar-labial angle. This scar is very forgiving, and I have used it with good results in patients with a history of keloids.

4-1 African American rhinoplasty

The most common approach performed for a primary African, Asian, or Latin rhinoplasty patient consists of an open tip with use of a septal strut, lower lateral cephalic trim, and removal of the fibrofatty pad collection at the crural dome. Lateral nasal infracture is used to blend the width between the tip and radix. Typically, the dorsum is left at its native height or is augmented with a cartilage or dermal fat graft onlay, depending on the patient's desired aesthetic endpoint.

Face Lift and Soft Tissue Restoration With Autologous Fat Grafting

Darker-skinned individuals have a tendency to age prematurely in some areas and late in others as a result of adipose tissue atrophy, bone remodeling, and gravitational soft tissue changes. Individuals of African heritage tend to manifest signs of aging in the deeper muscular layers of the face, with sagging of the malar fat pads toward the nasolabial folds. The folds become prominent and cheek ptosis is noted. Given the thicker dermis and subcutaneous tissue of some darker racial/ethnic groups, combined with infraorbital hypoplasia, midface aging can occur at an earlier age. For all the reasons mentioned earlier, rhytidectomy in skin of color can often be deferred or even avoided, given the availability of minimally invasive technology. However, there are appropriate indications for soft tissue repositioning and correction of facial rhytids in darker skin. The challenge I face is the nature of the procedure and the increased risk for adverse events. In particular, I know that hypertrophic and/or keloid scar formation may be exacerbated by increased skin closure tension, foreign body reactions or inflammation, and the patient's genetic factors. Therefore a simple skin-tightening procedure can be the start of disfiguring scars, as you can see on p. 105.

I have found that the use of progressive-tension sutures in this patient group helps to diffuse the ultimate resting tension on the periauricular skin closure. In addition, focusing on deep tissue repositioning helps to decrease the reliance on "tight" skin closure. In addition, I prefer to use nonabsorbable suture for the middermal to superficial dermal closure, which I remove within the first 7 to 10 days. Finally, I remove significantly less redundant skin than in a white patient to minimize skin tension.

This woman illustrates the result of a “lunchtime” skin lift. One can see how skin tension can lead to devastating complications. She is seen less than a month after surgery.

The patient is shown 6 months after a secondary face lift using a SMAS plication with conservative skin excision and internal progressive skin tension sutures. It is important to note the limited skin undermining, exposing only the lateral aspect of the midface–malar fat for suture plication.

My preferred facial rejuvenation procedure is the SMASectomy or SMAS plication procedure, especially in skin of color, allowing composite preservation and repositioning of soft tissue, but a variety of other approaches can achieve good results as well. The key is to reduce the provoking factors for poor scar in skin of color—primarily unrestricted tension. If I am ever in doubt or the patient has a questionable history of keloid formation, especially on the earlobe, I will either defer a face lift or consider an isolated postauricular approach, because the scar is easier to camouflage and/or treat with an intralesional steroid injection.

This second face-lift example is a woman who presented more than 2 years after a SMASectomy face lift, with autologous fat injection to the nasolabial folds and marionette grooves. The patient has a natural, well-maintained result that avoids the scar issues seen in the patient on p. 105. This case illustrates the importance of not placing the skin under excessive tension.

Fat Grafting

Autologous fat grafting can be performed alone or in combination with other procedures, using a variety of anesthesia options, including a local anesthetic only. I prefer to use the lower abdomen or flank as the primary donor site. Injection of tumescent local anesthesia, 60 ml 1% lidocaine with epinephrine 1:100,000 diluted into 250 ml normal saline solution plus 10% bicarbonate. Accordingly, the recipient site

is anesthetized using 1% lidocaine with epinephrine. Fat is aspirated using the Byron instrumentation (Byron Medical, Tucson, AZ), which offers graded cannulas. The harvest is then concentrated using a Telfa pad, strainer, or centrifuge, depending on the setting. Typically, 25% more volume than needed is injected. Care is taken to avoid bolus injection, and a microdroplet technique is used. The fat is injected into the subcutaneous layer accordingly. The puncture sites on the skin are not sewn but rather closed with Steri-Strips or a simple gauze covering to prevent suture marks that could hyperpigment during the healing process.

It is vital to use some form of silicone sheeting and/or scar massage during the acute healing phase, usually for the first 4 to 6 weeks or more. I typically see these patients two or three times during the first 6 weeks to assess for any evidence of scar hypertrophy or keloid formation. If there is evidence of such a scar process, intralesional steroid injections are very effective.

Adjunctive Nonsurgical Procedures

Laser

Skin resurfacing in skin of color can be very challenging, but the delayed nature of aging makes some of the light-based technologies an attractive option. In addition, the use of less-invasive technology can be coupled with minimally invasive surgical and nonsurgical technologies to provide the best of all worlds for this specific patient group. Although traditional ablative technologies such as CO₂ laser resurfacing may pose challenges to the treatment of darker skin, the newer wave of fractional and nonablative modalities offers significant benefits. Skin of color features the unique paradox of offering inherent protection from actinic damage, dense sebaceous support to lubricate the skin, and relative thickness, making it very nice to work with in all forms of handling. Yet it is much more prone to postinflammatory hyperpigmentation and adverse scar formation with resurfacing.

The primary indications for laser therapy in skin of color include hair reduction and treatment of dyschromia, texture irregularities, and scars. There are several critical considerations when considering laser treatment in these patients. The basics must be followed, such as shaving hair before laser hair reduction to avoid excessive energy uptake in surface hairs that can cause severe burns. In addition, many cases benefit from a patch test treatment before undertaking the definitive first treatment. Dermabrasion is really the benchmark for skin resurfacing in skin of color; it has been used for more than a century.

This patient is seen before and after two sessions of dermabrasion to treat severe forehead dyschromias. The technique is relatively low technology and offers the technician depth control and accuracy in uneven pigmentation cases, as this case demonstrates. I often use dermabrasion for treatment of active or chronic acne. This technique can be employed as a pretreatment before laser resurfacing or hair removal.

Before any resurfacing, it is vital to have patients use strict sunscreen protection of at least SPF 20 for 2 to 4 weeks before the treatment. In addition, although hydroquinone and retinoic acid use is beneficial for preparation of the skin and control of pigmentation after the treatment, patients typically defer retinoic and hydroquinone treatments for 1 week before and after resurfacing. During the treatment, two-phase cooling is vital to prevent thermal postinflammatory hyperpigmentation. To prevent complications, it is vital to respond quickly to a patient complaint of pain; a disproportionate complaint of pain is an automatic indication to halt treatment and reconsider the approach. Before the procedure, the need for realistic expectations is discussed with patients so they will understand that the treatment process will likely require a full year or more to achieve the greatest level of correction or enhancement.

The concept of selective photothermolysis is a concept developed in 1983 by Anderson and Parrish. The concept is vital to the understanding of skin of color. Fractional laser technology and nonablative capabilities are very attractive, given the tendency for energy to focus on melanin. With the gridlike effect seen with fractional laser treatment, there is less absolute injury and areas that are spared to aid in dermal recovery.

This woman with Fitzpatrick type IV skin requested treatment of active acne and related scars. Her acne scars were initially treated with three rounds of dermabrasion. Once the acne was brought under control, a combination of nonablative and ablative laser resurfacing was performed with the use of the Palomar fractional erbium laser system. The wavelengths used were 1540 nm for nonablative treatment, two sessions, and 2940 nm for ablative treatment, one session. The 6-month post-operative results are shown. Her regimen following skin resurfacing consisted of applications of silver sulfadiazine during the 5 days of reepithelialization, sunscreen protection at all times, and generalized cleansing of the skin. After 2 weeks, the patient used skin bleach (fluocinolone/hydroquinone/tretinoin [Tri-Luma] was preferred) for 4 to 6 weeks.

Fillers

The use of fillers in skin of color has many advantages and enjoys the same safety and efficacy profile seen in white patients. Because of the increased thickness of patients' skin and the darker pigment, the injection of product into the dermis tends to blend very well. In addition, longevity of effect appears to be at least the same if not greater in skin of color.

Based on my research with Dr. Grimes, I have found that several points should be considered regarding injectable fillers. In particular, the primary goal of any injection in skin of color is to minimize the number of needle perforations to the epidermis to reduce the risk of postinflammatory hyperpigmentation. In addition, it is important to inject the material into the deeper dermis to minimize the risk of dermal-epidermal separation, which can lead to epidermolysis and postinflammatory hyperpigmentation. Therefore our preferred technique, when possible, is linear threading with a 1- or 1.5-inch needle. To our knowledge, and based on a review of the current literature, there have been no reported cases of keloid or hypertrophic scar formation after the injection of hyaluronic, hydroxyapatite, or collagen fillers. Synthetic fillers are extremely advantageous in individuals of color who do not want to undergo surgical intervention. In particular, volume restoration to the midface can be readily achieved with a combination of deep injection to the submalar and tear-trough regions. In addition, the nasolabial folds and marionette grooves are further filled and corrected. Finally, with mild jowl formation, the prejowl sulcus can be filled, giving an appearance of a “liquid face lift.”

In patients with few rhytids, significant results can be achieved by injecting hyaluronic acid into the nasolabial folds, prejowls, and marionette grooves.

Concluding Thoughts

The use of expanded techniques in persons of color can lead to very safe, predictable outcomes. The material presented can form a framework for both clinical application and scientific investigation.

Clinical Caveats

Rhinoplasty

The surgeon reviews family photos when possible as a guide in planning intervention.

Overprojection and overrotation of the nasal tip should be avoided.

Postoperative deep tissue steroid injections should be planned.

An open incision is placed at the nasal–upper labial junction, in the natural shadow.

The use of morphing software to demonstrate potential results may lead the patient to have false expectations of what is possible, leading to patient dissatisfaction.

Autologous Fat Grafting

Excessive skin resection and/or tight skin closure must be avoided.

Absorbable suture closure on superficial skin should be minimized.

Soft tissue restoration should be seen as a primary tool; face lifting is secondary in skin of color.

Adjunctive Nonsurgical Procedures

A pretreatment patch test for laser patients is advisable.

Laser settings should be conservative.

Dermabrasion is the benchmark procedure for skin resurfacing.

Filler is injected into the deep dermis.

Fillers can serve as a supplement or substitute in facial rejuvenation.

Annotated Bibliography

Baker DC. Lateral SMASectomy, plication, and short scar facelift: indications and techniques. Clin Plast Surg 35:533-550, 2008.

This review of less-invasive face-lift techniques is outlined by a single surgeon. The focus is on significant results with less scar burden, a concept that is particularly appealing to persons of color.

CHAPTER 5

Photographic Essentials in Aesthetic Surgery

FARZAD R. NAHAI, WILLIAM Y. HOFFMAN

Photography and plastic surgery are inextricably intertwined, both in history and in today's practice. The development and popularization of photography in the 1800s gave people a new medium by which to measure, perceive, and evaluate themselves. Even for people of modest means, a photographic portrait was a special event, taken by itinerant photographers who carried their equipment with them. Most small towns had a photographic studio offering portraiture at a moderate cost. Certainly, popular photography had and still has a role in the general public's perception of themselves and can arguably be linked to the development of plastic surgery. Images of youth, beauty, and health pervade our daily lives. Often these photographic images are brought to the plastic surgeon as a representation of a patient's aesthetic goal.

Our patients are keenly aware of our reliance on photography as a diagnostic, documentary, and assistive tool. Photographs serve as records and legal documents. Because so much of plastic surgery is visually driven and amenable to photographic documentation, it is critical that we have a formal understanding of photographic techniques and strive for standardization of methods. We must apply these standard methods when producing photographic documentation in plastic surgery so that we have the means to accurately and adequately record patient outcomes and to compare preoperative and postoperative results. The recent advent of digital photography and its revolutionary effect on image creation has had a significant impact on the field of plastic surgery. This new technology has expanded our capabilities for photographic documentation, storage of and access to photographs, and even patient consultation.

History

In 1839, the process of making photographs, first named the *daguerreotype* after Louis Daguerre, was introduced; the remarkably clear images were called “mirrors with a memory.” It was in that same year that Sir John Herschel coined the term *photography*, which is derived from the Greek words for “light” and “writing.” The popularity of photography grew, and soon physicians of that era were using this new medium to record clinical conditions. In 1845, Gordon Buck, a New York surgeon, was the first to create a clinical photograph, a daguerreotype of a leg fracture. However, the original daguerreotype was only capable of producing a single photograph—in a sense an original piece of art that could not be duplicated. The wet-plate technique, introduced by Frederick Scott Archer in 1851, made photographic prints possible. With this new capability, Dr. Buck was able to take multiple photographs of his cases, including cleft lip repairs.

The next big step forward was the development of the dry-plate technique and celluloid film. George Eastman pioneered the mass production of film that could be stored in a roll. In 1881 he founded his company in Rochester, New York, which later became Eastman-Kodak. The first roll camera, the Kodak, was then introduced by Eastman in 1888 with the slogan “You push the button—we do the rest,” representing the birth of snapshot photography.

Photography Basics

Before addressing the issue of photography in plastic surgery, surgeons must have a basic understanding of how photographs are made and what equipment is needed to produce high quality images. These basics are applicable to both 35 mm film photography and digital photography. Today most plastic surgeons have adopted digital photography. In this introduction we will discuss the camera, the digital sensor, lens, and flash. A discussion of film is included as a historical reference and as a foundation to understanding the common terminology still used in digital photography.

The Camera and Optics

Capturing an image involves exposing the medium onto which the image is recorded (that is, a digital sensor chip or silver-based film) to an appropriate amount of light. The camera or lens contains a shutter that controls the amount of time that light is allowed to strike the medium. Within the lens is a diaphragm that acts much like the iris of the eye; it controls the exposure, or amount of light, that enters the film chamber (or the chip, in a digital camera). The shutter and diaphragm act in concert to control the exposure of the subject onto the recording medium.

Single-lens reflex (SLR) cameras contain a mirror in front of the shutter that projects the exact image seen by the lens to the photographer through a viewfinder. In “point-and-shoot” cameras, separate optics permits the photographer to see what the camera is “seeing.” In today’s digital point-and-shoot cameras, images gathered through the lens are also seen on liquid-crystal display (LCD) monitors.

The characteristics of the lighting environment dictate how much light is exposed to the recording medium (chip or film) and the duration of exposure. A built-in light meter in the camera calculates the best-fit exposure to record that scene. Exposure is controlled by shutter speed and aperture. *Shutter speed* is generally measured in fractions of a second ($\frac{1}{250}$ sec, $\frac{1}{500}$ sec, $\frac{1}{1000}$ sec) and refers to the amount of time that the shutter within the camera is open. *Aperture* refers to the diameter of the

opening of the diaphragm and is commonly referred to as the *f-stop* or *f-number*. The f-stop is typically described in terms of $f/4$, $f/5.6$, $f/8$, $f/11$, and so forth. It is an inverse relationship: the larger the f-number, the smaller the aperture, and therefore the less light that is allowed in. With the many available shutter speeds and f-stops, there are numerous metering combinations that result in the same exposure. This is an important concept to comprehend in understanding how optics and camera settings can affect photographs.

The concept of *depth of field* is critical in clinical photography. It refers to the distance in front of and behind the focal plane, or the subject in focus in the photograph, that remains in focus. A shallow depth of field means there is a small distance about the focal plane that is in focus; as the depth of field increases, so does the area in front of and beyond the focal plane that is in focus. Three factors control depth of field: the aperture, subject distance, and focal length of the lens. Assuming a fixed focal length and subject distance, the aperture may be manipulated to minimize or maximize the depth of field. A large aperture ($f/3$) has a shallow depth of field, thus making anything beyond or in front of the subject blurry. As the aperture increases (for example, to $f/8$), the depth of field lengthens and more objects within a certain range of the focal point will appear in focus.

The three photographs above are good examples of the aperture-setting effect on depth of field. The first photograph was taken at $f/4.5$, the second at $f/8$, and the third at $f/16$. These chess pieces were set 24 inches from the camera and 1 inch from each other. Notice how much more of the photograph is in focus with the larger aperture setting on the right.

This is a clinical example of the same phenomenon. The photograph on the left was taken at $f/2$ and the one on the right at $f/8$. Notice how in both photographs the tip of the nose is in focus, but only in the larger-aperture photograph are the eyes and forehead also in focus. This effect, which is based on aperture setting, must be considered when selecting camera settings in a clinical situation. In general, clinical photographs should be taken with a larger aperture number ($f/8$ or $f/11$) (smaller actual aperture size) to ensure crisp focus throughout.

Barrel distortion is a lens effect that causes images to be *spherized* at their center. This type of distortion typically occurs with wide-angle lenses and at the wide end of zoom lenses. The photographs above show an example of barrel distortion with a wide-angle setting. The photo on the left is taken with an 80 mm lens and the one on the right with an 18 mm lens. One can notice the robust effect a change in focal length alone can have on an image. In the clinical setting, subjects can appear rounded and centrally full or projective when, in fact, they are not.

The three-dimensional opposite of barrel distortion, *pincushion distortion*, is a lens effect that causes images to be pinched in their center. This is associated with the telephoto end of zoom lenses or with the addition of a telephoto adaptor. Because of these types of distortion, wide-angle and zoom lenses are not recommended for clinical use.

Lenses

Lenses are made up of multiple elements, usually individual concave and convex glass lenses, the combination of which gives a lens its operating characteristics. Lenses come in many different sizes, called *focal lengths*, based on the distance in millimeters from the posterior element to a point at which parallel rays of light are focused. The characteristics of a lens are largely based on its focal length.

A “standard” lens (one that does not magnify or diminish the size of an image) for any film or sensor size can be calculated based on the diagonal of the film. For example, the calculated standard lens size for 35 mm film is 35 by 24 mm, making its diagonal 43 mm. (Despite this calculation, 50 mm is the accepted standard.) This is an important concept to understand when using interchangeable lenses on digital SLR cameras, which for the most part have sensor chips that are smaller than the dimensions of 35 mm film. As a result, the standard lens on a digital SLR camera would, in fact, be a shorter focal length. Conversely, the same lens on a digital SLR will be the equivalent of a longer focal length 35 mm lens; for a digital sensor that is two thirds the size of 35 mm film, a 60 mm lens would behave like a 90 mm lens on a digital camera. As digital sensors are developed that increase in dimension and match the size of 35 mm film, this discrepancy will no longer be an issue, and lenses can be freely interchanged without concern for converting focal length (at present such sensors are available but are prohibitively expensive). For point-and-shoot cameras, the range of a lens is usually expressed in “35 mm equivalent” to make comparisons easier.

Lenses less than 50 mm in focal length are considered *wide angle*, and lenses greater than 50 mm in focal length are considered *telephoto*. *Zoom* lenses can traverse a range of focal lengths. Wide-angle lenses are good for panoramic/wide views, and telephoto lenses are good for viewing objects that are far away. Later in this chapter we will discuss how shutter speed, aperture, and lens optics affect the taking of photographs and how these apply to the plastic surgery setting.

Flash

The flash plays an integral role in photography in the plastic surgery setting. Clinical photographs are taken indoors in variable lighting conditions. Therefore it is important to have a reliable light source, comprehend how it works, and understand how flash photography can affect the images produced. The intensity of the flash determines the f-stop that can be used; the f-stop (as discussed earlier) determines the depth of field. Proper use of the flash enables small apertures and more depth of field.

Too much flash and improper aperture settings can result in washed-out photographs that lack definition and exhibit poor color quality.

Flashes on point-and-shoot cameras are typically mounted on one side of the camera at a relatively short distance from the lens. SLR cameras have a mount for the flash, usually above the lens, in addition to connectivity capabilities to operate multiple flashes at a distance from the lens. This is important because multiple flashes eliminate shadows. The “red eye” effect of point-and-shoot flash photography is a symptom of the flash being positioned too close to the lens. Some cameras have features that correct for this problem.

In addition, attention must be paid to flash position relative to the lens because of the shadows that are cast. As demonstrated by these photographs, the shadows projected on the backdrop can have a significant deleterious effect on the composition of the photos, most notably on lateral and oblique views. A projected shadow should not be viewable in clinical photography. A simple rule of thumb is that the flash should be positioned on the same side as the anteriormost part of the patient, placing the shadow behind the patient, as in the figures on the far right.

Equipment for Clinical Photography

Camera

With current trends, a digital SLR camera is the optimal choice for clinical photography. The camera should have manual controls for aperture and shutter speed to maximize versatility and control.

The camera should have manual and autofocus modes and accept interchangeable lenses.

A digital camera should have a minimum of 3 to 4 megapixels; 6 megapixels is preferred for publishing and enlarging photos.

Although a digital SLR camera is best for a studio setting, the point-and-shoot digital cameras with a rotating LCD screen offer an advantage for intraoperative photo taking and awkward camera positions.

Lens and Flash

Quality fixed focal length lenses should be used: a 50 to 60 mm lens for the body and a 90 to 100 mm lens for the face.

The lens should be marked with reproduction ratios.

At least a top-mounted flash with through-the-lens metering should be used, but optimally a studio setup with multiple flash units to eliminate shadows is preferred.

A lens with macro capabilities should be used for closeup photographs.

Ideally, multiple flashes should be used to eliminate shadows. Twin flashes are available that mount on the camera and eliminate the problem of sidedness with single-source flashes. Otherwise, a dedicated space with flashes set up on either side of the subject, or a committed studio, is needed. The setup of a committed studio will be addressed later. Ring flashes, flashes that mount at the end of the lens, are used for macro-photography. These can decrease shadows; however, they tend to make contours difficult to distinguish so they are used principally for intraoral and dental photography.

Film

Although digital photography is the current norm and some major camera companies no longer make film-based cameras (Canon stopped in 2006), film has some advantages over digital images: 35 mm film has excellent resolution, comparable to digital cameras with 6- to 10-megapixel sensors. Having said this, today's digital cameras with resolutions as low as 3 or 4 megapixels offer adequate resolution for clinical use. Film also represents a stable record that cannot be altered or modified, as digital images can; when stored properly, it cannot be lost or erased. Photographs made on quality film (such as Kodak Kodachrome) can last up to 30 years when stored properly.

However, there are significant disadvantages associated with film photography when compared with digital photography:

Buying and processing film is costly.

Storage of prints, slides, and negatives requires significant space.

You cannot immediately determine whether the photographs adequately capture the desired documentation.

Copies are difficult to produce; digital scan copies are an option but are also difficult and time consuming.

Printed images are subject to degradation by dust, fingerprints, and aging.

Clinical photographic prints can be “borrowed,” never to be seen again, leading to permanent loss of a significant part of a patient’s photographic history.

Slides lose color over time, especially when used in bright projectors.

The methods of processing, color balance, and type of film affect the final image.

Digital Photography

Digital photography and imaging are the standard today, with cameras that are capable of excellent resolution, and computers that have increased storage and processing capacity to handle the larger files that result. Today digital cameras outsell film cameras. Yearly advances are being made in digital technology that continue to improve the quality of digital photographs. With the demand for digital photography in the marketplace, resolution has significantly increased and cost has significantly decreased. These two trends have been the driving force that has propelled digital photography into the majority of plastic surgery practices.

The advantages of digital photography to the plastic surgeon are numerous. Most plastic surgeons have adopted the digital method of creating, storing, viewing, manipulating, and presenting clinical photographs. The computers and software needed to view and store digital images are already in most offices. The revolving cost of film and processing is essentially eliminated.

Memory Card

A large-capacity *storage card* such as an SD or compact flash card (in effect, a digital camera’s “film”) can now be purchased for about the same price as purchasing and processing several rolls of film. These memory cards can be reused thousands of times before they need to be replaced. Several investigators have carried out detailed cost analyses of the financial benefit of converting from film to digital photography. As digital photography expands and film usage diminishes, market forces will likely increase the cost differences so that they favor the digital format even more.

Digital images, like any other form of digital data, can be easily copied, stored, displayed, and accessed. These images can readily be shared with colleagues for consultation purposes, either face to face or over the Internet. Images are also easily imported into presentations. Multiple informational tags (such as age, date, and procedure performed) can be stored with images to facilitate archiving, searching, and retrieving in large image databases (for example, for instant access to and display of all blepharoplasty cases). Digital images are easily copied, so all of this can be done without loss of the originals. These images can be easily printed so that pre-operative photographs can be displayed in the operating room and referred to during a procedure. An even more advanced method of having clinical photographs available in the operating room is to establish wireless connectivity between the imaging computer and an LCD monitor, bypassing the need to print photographs.

The advantages of digital photography have also had a significant impact on patient and resident education. With the incorporation of LCD monitors and the playback capabilities of digital cameras, digital photography provides instant feedback on clinical photographs. Any problems with lighting, patient positioning, or composition can be immediately identified and rectified. With digital images and the proper imaging software, one can create simulations of operative results and facilitate patient consultations. These image manipulations can also help the plastic surgeon with operative planning and may reveal certain unwanted aesthetic effects of a surgical procedure before the procedure is performed and perhaps help to avoid undesirable outcomes. In addition, most digital cameras are capable of recording digital video that is easily played and can be used for teaching purposes.

Advantages of the Digital Photography Format

- The ability to store, organize, copy, share, manipulate, and import photographs into presentations, all with unparalleled ease
- No revolving cost of developing film
- Resident teaching and patient education and consultation are facilitated
- Immediate feedback on photographs taken so no loss of opportunity for the perfect shot
- Digital images are stable data that do not take up physical space like prints and slides

The Digital Imaging Setup

The general principles and basics of photography discussed earlier apply to digital photography. There are, however, several key differences between digital and film photography, principally in the creation, storage, manipulation, and production of photographs. We will discuss the differences that are applicable to clinical photography.

Camera Systems

There are two principal types of digital cameras on the market today: point-and-shoot models and digital SLR models. Digital point-and-shoot cameras were the first universally available and affordable type of digital cameras and are currently in common use among plastic surgeons. Myriad models have a zoom lens, autofocus, and an integral flash. These cameras have various levels of programmability and versatility. The composed image is viewed on a small LCD screen and on a viewfinder in most models. In some models the viewfinder tilts and swivels, allowing the photographer to see the image from a different angle than the camera does. This can be particularly helpful for intraoperative photography.

Digital SLR cameras are now universally available and are made by many camera companies. Their prices have decreased considerably, making them more accessible for the casual photographer. As with film SLR cameras, digital SLR cameras use interchangeable lenses, accommodate top-mounted flashes that can perform metering through the lens, can control multiple distant flashes, and permit the user much more versatility. With the SLR camera the photographer can use manual controls and fixed focal length lenses, which are generally of significantly better quality than the lenses of point-and-shoot cameras. These features make the digital SLR camera the optimal device for producing standardized photographs.

Instead of film, digital cameras render images via a sensing chip. Two types of sensors are common, one called a *charge-coupled device* (CCD) and the other a *complementary metal oxide semiconductor* (CMOS). The sensor is made up of a grid of *pixels* (short for “picture elements”); each pixel is a single-unit representation of the light falling on it. By comparison, on film, individual silver ions change with exposure to light. For example, a sensor with a pixel array of 2140 by 1510 would have a total of 3.34 million pixels, which is commonly referred to as 3.34 *megapixels*. As mentioned previously, the size of the sensor in comparison to standard 35 mm film dictates how images from lenses of different focal lengths will be rendered. The image cast by a 100 mm lens onto 35 mm film will be magnified to a degree based on the size difference between the sensor and 35 mm film. A sensor two thirds the size of 35 mm film will record the central two thirds of the image cast by a 100 mm lens and in a sense magnify the image, thus rendering an image comparable to that achieved with a 150 mm lens; $\frac{2}{3} \times 1.5 = 1.0$, hence the conversion for most digital SLR cameras is $1.5 \times \text{focal length}$ to get the 35 mm equivalent.

Digital cameras are categorized by the amount of megapixels they have. The number of effective megapixels in a given camera is directly proportional to the resolution (amount of detail that can be seen in an image). The more megapixels, the greater the resolution and the greater the detail of a given image. However, the final quality of a digital image also depends on the quality of the lens, proper metering, focus, and, if the images are to be printed, the printer and paper being used. In addition, the size of the pixels contributes to perceived resolution or sharpness; a digital SLR and a point-and-shoot may have the same megapixels, but the SLR will generally have a larger sensor with larger pixels, which captures more light and detail. Based on the capability to enlarge photographs and maintain detail adequate to the human eye, 35 mm film is roughly comparable to a 6-megapixel image.

Once the sensor captures an image, it is transferred through an analog to a digital converter for processing, a buffer, and then the storage card. During the course of processing images for storage, the images' raw data are compressed to varying degrees. Multiple compression algorithms exist, the most predominant being the JPEG (Joint Photographic Experts Group) format. Compression reduces an image file by 8 to 10 times with nominal degradation in image quality. The first save of a JPEG image does not cause poor quality at the highest resolution; however, any subsequent resave of the JPEG can degrade quality significantly if the proper settings are not used. Also to be avoided is multiple resizing of the image. Although JPEG format is the default setting on many cameras, for images intended for use in presentations and especially for publication, it is strongly advised that the image be saved in Tagged Image File (TIF) format with LZW compression as an effective, lossless method of maintaining image resolution.

9.5 mb raw

1.2 mb JPEG

380 kb JPEG

In these photographs, one image is in the raw format and the other two are JPEGs compressed to varying degrees. No appreciable difference can be seen between the “heavy” 9.5-megabyte raw image and the 1.2-megabyte and 380-kilobyte JPEG compressed images.

Also, compare the two JPEG compressed files with the zoom insets and note that both images are comparable with regard to resolution and detail in the magnified portion. These images remain 1.2 megabytes and 380 kilobytes, respectively, and further demonstrate the minimal effect of JPEG compression on image quality. However, note that all images that are printed in a publication (for example, all the images in this book) are printed in a *halftone* pattern (a multitude of minute, regularly spaced dots of ink; in this case, dots of four different colors), which may obscure any differences.

This process makes it realistically possible to store many digital images and facilitates handling (copying and moving) of individual photographs. There is a caveat, however: if you make changes on a given JPEG image and then save it in a JPEG format, multiple compressions will result in loss of detail and image quality. Therefore it is important to always save an original image and create another file for the image that is being altered so that multiple compressions and loss of detail do not occur. Most modern imaging software, such as Adobe PhotoShop and Apple's Aperture, preserves the original data by applying a set of instructions to altered images as opposed to making permanent changes, thus avoiding loss of information and image data and saving disk space. Of course, while this can preserve image quality, it is dependent on the user's handling this feature correctly. In clinical photography it is important for medicolegal reasons to always save an unaltered photograph.

Storage cards are removable storage devices housed within the camera that store processed images from the sensor. These are principally solid-state type storage devices as opposed to optical (CD-ROM) or magnetic (hard drive). They come in several different formats (such as compact flash card, secure digital card, and memory stick), memory sizes (which dictates the number of photographs that can be stored), and speeds (the rate at which information is written onto and read off of a card). Data from a storage card can then be downloaded to a computer either by connecting the

camera to the computer via universal serial bus (USB) or FireWire, or by removing the storage card from the camera and using a card reader. The method of transferring data is important to consider, because there are significant differences in the speed at which photographs can be downloaded. FireWire and personal computer memory card (PCMCIA) readers are the fastest methods to date and will make a significant difference in download times when managing many photographs at a time.

Peripherals and Data Storage

A back-up system for all digital photographs should be used routinely: one on-site backed up on a daily basis and one off-site backed up on a weekly basis.

A computer with a large-capacity hard drive should be used for storage with enough RAM to handle large photographic image files.

A monitor that is at least 15 inches is preferred.

A color printer should be used; the expense of photo-quality paper should be saved for when it is really needed.

A pen-driven, tablet-type touch pad (for example, the Bamboo; Wacom, Vancouver, WA) can be used for photo editing. This mimics the hand motions used in drawing much better than a mouse making edits and morphing easier.

A high-speed storage card that is 100× or more results in very fast photo reading and writing times, which is especially advantageous with large image files and transfers of a large number of photos.

The megabyte capacity of a storage card should best suit your needs. Too large and you may have too many photos to download at once. Just the right size and you can take many photos but be forced to download your photos on a regular basis.

A FireWire or USB 2.0 cable card adapter should be used to transfer photographs to the computer. These are the fastest methods currently available. More recently, Eye-Fi has introduced a wireless-capable SD card, obviating the need to remove the card from the camera to transfer photos.

Digital Imaging Software

Once an image has been transferred to the computer, appropriate software is needed to view, archive, edit, or print a photograph. Most operating systems today come with basic storage, viewing, and photo-editing software. Many additional applications are available with advanced features for viewing, archiving, and retrieving images. Specialty software is also available that allows the surgeon to easily manipulate and *morph* (short for “metamorphose”) photographs to mimic operative changes. A preoperative photograph can be manipulated to mimic an operative procedure, assisting the surgeon and patient in preoperative planning and consultation. The use of morphing software during the patient consultation will be addressed later.

As with film cameras, digital cameras are vulnerable to the same optical distortions mentioned earlier, in addition to a host of additional artifacts unique to digital photography. *Artifacts* (image distortions) based on image processing, and compression can occur, in addition to noise (the visible effects of an electronic error). It is important to know that the possibility for these phenomena exists, but a detailed discussion of them is beyond the scope of this chapter. Suffice it to say that in clinical digital photography these are unlikely to be encountered.

An organized approach to storage of photographs is essential. At a minimum each patient should have a folder for all of his or her photographs, but today there are numerous programs that allow attaching searchable key words, which can include diagnosis and procedure as well as demographics. Although this takes additional time during uploading of photos, it is well worth the effort later when trying to retrieve photos. Some examples include Canfield Scientific's Mirror; Extensis's Portfolio; Ulead's iPhoto; and ACDSee.

Recommendations for Photography in Plastic Surgery

The choice of digital camera should be based on several factors governing the ability to generate high-quality standardized photographs. The camera should have manual controls, accept interchangeable lenses, have the ability to control external flashes, and mount on a tripod. As noted above, an SLR is preferable for all of these reasons. Some point-and-shoot cameras have high-quality lenses, manual controls, multiple flash capabilities, and can take high-quality photographs, but there is great variability based on brand and model. Adequate clinical photographs can be taken with these point-and-shoot cameras, but SLR cameras offer more versatility and will produce superior images that are easier to standardize. Entry-level SLR cameras with a lens are now priced only a little higher than point-and-shoot models.

It is imperative that the surgeon develop a method of frequent and reliable backup of all images. A number of backup systems are currently on the market. Optimally, backup is done daily to a large storage device that is backed up locally, and on a less-frequent basis to a storage device physically located away from where the images are made in the event of a catastrophe (local system failure, virus attack, fire, earthquake) and loss of all data. Thus at a minimum the images are on three hard drives or other storage: the primary computer or server, a backup drive on-site, and a backup off-site.

A top-mounted flash, or better yet, a studio setup with multiple floor- or ceiling-mounted flashes, is ideal to minimize shadows and produce studio/portrait-quality photographs. As space for a studio is not always available in all office settings, an examination room can serve as a dedicated photography area using a painted wall or curtain as a backdrop. Mountable twin flashes are available in lieu of floor-mounted flashes.

This is an example of a digital photography studio. The camera is set up with a combination of floor- and ceiling-mounted flashes and a neutral background. In the digital studio, a computer with the appropriate software and a printer should be available for viewing, editing, and printing photographs. When editing digital photographs with morphing or “paint and draw” techniques, the use of a digital tablet and stylus mimics natural hand motions much better than a mouse. Using a tablet for such tasks will greatly facilitate their execution.

Requirements for a Digital Photography Studio

A room at least 10 by 12 feet
A uniform color backdrop that can be changed, depending on the patient's skin tone
The camera mounted on a tripod
A swivel sitting stool so the patient can sit for facial photography
A floor mat indicating patient foot positions for body photography at 45-degree oblique, 90-degree lateral, and 180-degree posterior views
Multiple floor- or ceiling-mounted flashes to eliminate shadows (two flashes for the background and two flashes for the subject)
A computer with appropriate storage, retrieval, and editing software, a color printer, and stylus-driven tablet-type touchpad for photo editing
A monitor of at least 15 inches
A stylus-driven touch pad for photo editing (this is better at mimicking natural hand movements than a mouse is)

Managing Photographs and Text for Presentation

Frequently, clinical photographs are used for presentation purposes. Before any clinical photograph with personal identifying features is used in presentation format, consent must be obtained from the patient. If consent has not been obtained, the photographs should not be used in an educational or public forum.

Any time clinical photographs are used for presentation, education, or demonstration, the photos should be clear without distracting elements, and they should be large enough that when projected they can be easily viewed. A good rule of thumb is that any photograph should not be less than one third of the total projected image. If the photograph is too small, it cannot be adequately appreciated and will not succeed in conveying the desired point of the photograph.

Some useful image-saving guidelines are as follows:

For presentations/projection on a screen: *The maximum pixel width of the screen is currently 1600 pixels, so an image on half of a "slide" should be about 800 pixels for optimal clarity.*

For print production: *For each inch that you intend in printed image width, multiply by 300 and round up. Thus a photo that is to print as 3 inches wide $\times 300 = 900$ pixels wide minimum. It is also best to let the publisher downsize and crop the image to your instructions.*

Photographic Standards in Plastic Surgery

General Concepts

Many excellent articles have been written on the photographic standards for clinical photography.

Whether or not your office has a studio, patients should be in a private and comfortable setting for clinical photography. All jewelry and makeup should be removed for facial photographs. Long hair should be held back off the face, forehead, and ears. Clothing should be removed, and disposable low-profile privacy garments used in body photography. A uniform nonreflective background of blue, grey, green, or off-white should be used. The choice of background color depends on the patient population and should be matched to maximize contrast with skin tone. The backdrop can be a painted wall or door, a studio backdrop, or common bed sheet or towel easily found in the hospital setting. The subject should be positioned 18 to 36 inches from the backdrop.

Techniques for Taking Clinical Photographs

A dedicated photography area or studio is ideal for picture taking, if possible.

Patients should be made to feel comfortable having their photographs taken, and permission should always be solicited.

Photographs should be taken in a private, well-lit setting; patient comfort and dignity must be maintained.

Recommendations for standardizing all photos of particular body regions should be followed with regard to composition, lens choice, subject distance, and alternate views. An aperture of $f/8$ is used to lengthen the depth of field and still allow enough light for good exposure.

The grid screen in the viewfinder is used to help with patient positioning.

The lens is set to a fixed focal distance; then the camera is moved to bring the subject in focus. This helps in standardizing photographs and facilitates preoperative and postoperative comparisons by maintaining a constant reproduction ratio.

A uniform background will enhance the subject outline and improve contrast—darker colors for light-skinned individuals and lighter colors for dark-skinned individuals.

Flash position should be monitored to hide shadows.

For intraoperative photographs, the operative field should be clean, distracting elements minimized, and technical demonstrations simplified.

For facial photography, the patient should wear minimal or no makeup. Jewelry and eyeglasses should be removed, and shirt collars should not obstruct the view of the neck.

For body photography, privacy garments should be worn, with no street clothes.

A normal or basic JPEG setting will maintain good photo quality and keep image files down to a manageable size (less than 1 mb, preferably under 500 kb)

The lens should be held at the same level as the area being photographed. A viewfinder equipped with a grid screen is very helpful in determining proper alignment, as demonstrated below.

Fixed focal length lenses should be used, avoiding the distorting characteristics of wide-angle and zoom lenses. If a zoom lens is used, it should be high quality and have a focal length range much larger than what would be used clinically to avoid the distorting effects at the ends of its range. The same point on the zoom can be used for reproducible results. The size and focal length of the lens used is based on the part of the body being photographed. The lens choice should position the photographer at a comfortable working distance from the patient and allow for adequate composition of pertinent features. The photographer should establish standard anatomic landmarks to be included in each given view. A subject distance from the camera lens or a reproduction ratio to fill the frame with these landmarks should also be determined. The reproduction ratio (for example, 1:2, 1:4, or 1:10) can be found on most SLR macro lenses. These ratios represent the size of the subject and the size of its image on film, or in other words the size scale to which the photograph renders the subject. A 1:1 ratio represents a life-size image, and so on. These ratios are not valid when a 35 mm lens is used with a digital SLR because of the magnification; thus a safe rule of thumb is to set the camera 3 feet away to photograph the patient's face and 6 feet away to photograph the patient's body.

As much as possible, intraoperative photographs should adhere to the recommendations for photographs taken outside the operating room. The operative field should be cleaned, fresh border towels placed to frame the subject, and any distracting items removed from the field. Operating room lights are intense spotlights and should be turned away from the field during photography to facilitate accurate metering and exposure. If operative techniques need to be demonstrated and instruments are visible in the photograph, instruments with a dull finish should be used (alternatively, bone wax can be applied to shiny surfaces) so that reflections are minimized. All demonstrations should be simple, with minimal distracting elements. Photographs should be taken at right angles to the patient and from the same vantage point, usually with a wider orientation photograph before any close-up photos are taken. Before any series of photographs is taken of a patient, we strongly recommend that the patient's name and the date be recorded. This can easily be done by photographing the nameplate from the patient's chart before beginning the photographic series.

The box presents a helpful mnemonic device to keep in mind while taking clinical photos.

Mnemonic Device for Photographic Consistency

FLASHBACK

- F *Framing* anatomic landmarks and proper *focus*
- L *Lighting*
- A *Aperture* setting
- S *Subject* distance and *shutter speed* setting
- H *Hold* consistent reproduction ratio
- BACKground

All aspects of clinical photographs should be kept consistent, including use of the same camera, lens, lighting, film, patient positioning, and image framing. By following the preceding guidelines and adhering to the standards that follow, you will obtain excellent photographs, ensure reproducibility, and facilitate valid preoperative and postoperative comparisons.

Photographing the Face

Full-face photographs should be taken with a 90 mm lens (or digital equivalent) and should include the neck and ears. A reproduction ratio of 1:9 is used. The hair should be pulled back, jewelry removed, and no makeup or a minimal amount worn. Shirt collars should not obstruct the view of the neck. Anteroposterior views should include the clavicular heads and the top of the head. Eyes should be looking straight ahead, and the mouth should be relaxed. Additional images should be taken with the face in animation to document facial nerve function preoperatively. Oblique photographs should be taken with the medial canthus of the distal eye just meeting the nasion (both left and right views should be photographed for oblique, lateral, and tilted-down positions). The patient's whole body should be turned, not just the head,

to avoid torsional changes in the appearance of the neck. Lateral views are taken with the philtral columns aligned along the Frankfurt horizontal (a straight line from the tragus to the infraorbital rim) and kept parallel to the lower border of the photograph, with the eyes looking straight ahead. If a single flash is used, the flash should be oriented on the same side as the nose to avoid shadows.

An additional lateral tilted-down view is taken with the patient gazing downward to create a double chin.

Close-up views of the face are obtained with the same-size lens, using a reproduction ratio of 1:4. These views are better at demonstrating facial rhytids and more detail about specific facial areas. The face is divided into upper and lower halves. The upper half is from just above the brows to the upper lip. This provides a closer look at the eyes, cheeks, and nose. Consider photographing the eyes with a lower flash setting or using only ambient light for improved detail of periocular structures. A smaller aperture ($f/11$ or $f/16$) will give better depth of field at closer range. Photographs of the lower half of the face extend from the middle of the nose to just below the chin, giving close-up views of the nasal tip, mouth, chin, and neck. The same guidelines apply to patient positioning as for full-face views.

Photographing the Nose

Photographs of the nose will also require a 90 mm lens. The same rules for the face apply for the anteroposterior, lateral, and oblique views of the nose, the only difference being that the framing is closer, from the top of the forehead to the bottom of the chin, with a reproduction ratio of 1:4. A basal view of the nose should also be included. This is done by lining up the top of the nasal tip with the medial canthi, and provides information about nasal base width, the nasal tip, and the dorsum. Additional views specific to the nasal tip can be obtained with the “worm’s eye” (basal) view, lining up the top of the nasal tip with the level of the upper eyelid crease. This view obstructs the dorsum but can provide more information about the columella, septum, nasal sills, and tip symmetry. A lateral smiling view can be done to help assess the effects of facial animation on the nasal tip.

Photographing the Ears

Photographs of the ears include the standard anteroposterior facial shot in addition to a posterior view with the hair pulled up. Close-up lateral views of the ears with a reproduction ratio of 1:3 show details of the helixes, concha, tragus, and lobule.

Photographing the Teeth

Quality standard photographs of the teeth and occlusal relationships can only be obtained with a ring flash and cheek retractors. Anteroposterior and oblique views should include the nasal tip and chin.

Photographing the Body

Because photographs of the body cover a larger area than those of the face, a 50 mm focal length lens at a distance of about 3 to 6 feet from the subject is used. The same recommendations for lighting, flash position, and background apply. Because patients will be in varying states of undress, it is very important to ensure a comfortable and private environment for photography. Standard disposable cover garments are used so that aesthetic features and body contours can be more easily seen while simultaneously maintaining patient dignity.

For the majority of body photographs, a reproduction ratio of 1:12 is used. A floor mat that has various feet positions marked for oblique, lateral, and posterior views is helpful. In this way patients can simply place their feet in the specified areas so they are lined up properly for the photographs.

Photographing the Breasts

When the patient's breasts are to be photographed, the patient should be instructed to hold her arms comfortably at her sides with her back straight and shoulders slightly rolled back but not pulled upward. The shoulders and clavicles should be included, as well as sufficient space below the bottom edge of the breast. Anteroposterior, lateral, and oblique (the patient turned 45 degrees) views should be obtained. Patients should turn their whole body rather than twist at the hips for oblique views. In a transverse rectus abdominis myocutaneous (TRAM) reconstruction, the breasts and abdomen down to the level of the upper thigh should be included so the umbilicus and pubis can be seen.

Photographing the Abdomen

The abdomen is framed from the inframammary fold to the upper thigh. The arms are held above the level of the photograph, folded across the chest. Anteroposterior, lateral, and oblique views are taken. Additional lateral views with the patient bent 30 degrees at the waist can be helpful for assessing excess skin and overhang. Privacy garments should not cover the location of any incisional scars.

Photographing the Hips and Thighs

When photographing the hips and thighs, the patient's arms are held folded across the chest, and the feet are separated to show the full contour of the medial thigh. The hips and thighs are framed from just above the umbilicus to just below the knees. Anteroposterior, lateral, oblique (of the front and back), and posterior views are taken.

Photographing the Arms

The arms are photographed individually while the patient is bent 90 degrees at the elbows and abducted 90 degrees at the shoulders. The patient should be upright, and anterior and posterior views should be taken. The head is cropped to maintain anonymity and focus attention on the arms.

Digital Imaging and Morphing

Imaging and morphing software can be an excellent teaching tool for use with a patient who will be undergoing plastic surgery. If a digital format is used and imaging software is part of the patient consultation, the surgeon should sit down with the patient at the computer monitor after all appropriate photographs have been taken. Viewing the photographs with the patient allows the surgeon and patient the opportunity to analyze areas of concern and joins them in preoperative decision-making. With effective use of a software program, the surgeon can demonstrate the possibilities and limitations of a surgical procedure in a very realistic visual manner. Sometimes these consultations can expand a patient's desire for additional procedures. Caution and judicious use of manipulating software must be exercised so that one does not create unrealistic expectations and undermine the efforts to educate and

prepare patients for their surgical procedure and postoperative prospects. It is mandatory that the original images be saved in an unedited format.

Legal Issues

Clinical photographs, although considered a part of the medical record, represent a unique incursion into a patient's privacy. Therefore plastic surgeons should recognize that patients have specific rights that apply to the taking and use of these photographs. Consent for taking photographs or video recordings of any sort should be obtained and kept on record. This should also include the consent for publication and display of these photographs. An example of photographic consent forms is shown on pp. 144 and 145. In general, publication in a journal, textbook, or website should be done with the patient's specific consent for that use as well as the general consent form obtained in the office. It is recommended when obtaining consent to publish patient images on the Internet that the precise name of the website be included in the consent form. Any images submitted to be displayed on the web should be rid of any metadata that could identify the patient. It is safest to simply rename all image files with generic terminology and indexing, and never use names.

There have been cases of photographs being taken of unconscious patients without their consent; these are a clear invasion of the patient's privacy. The person who takes the photographs has legal ownership of the photographs unless the photographer is in the employ of the plastic surgeon. Computer images are considered part of the medical record and as such should not be deleted or destroyed. To do so can incur civil or even criminal charges.

Legal Safeguards

Consent should be obtained for all clinical photography.

Specific expressed consent should be included for publication, display, or presentation of any photographs, especially those with identifiable elements (this includes tattoos or birthmarks as well as facial features).

Special measures should be taken for photographs to be published online.

A statement should be included with any altered or morphed image given to a patient that it is not a guarantee of an operative outcome; in addition, a method of authentication should be used.

All patient photographs should be kept as a part of their medical record and treated as such.

Patient photographs should not be destroyed.

PLASTIC SURGERY PHOTOGRAPHY CONSENT

Page 1 of 2

I hereby voluntarily grant permission to _____
and/or their designated employees to take and use any preoperative, intraoperative, or postoperative
photos of myself for purposes of record, research, education, and medical publication, as well as
assisting others in making their surgical decisions. Any of these uses may be eliminated from
this form.

I further understand that no form of compensation shall become payable to me for the use of these
photographs.

I hereby release _____
and its agents from any and all claims and demands arising out of or in conjunction with the use of
these photographs.

Common Errors in Clinical Photography

Zoom or wide-angle lenses should not be used at the limit of their range.

For facial oblique views, the entire body should be turned, not just the head, so the neck contour is not distorted.

Distracting backgrounds and dirty operative fields interfere with clear patient photography.

The pincushion effect of closeup photography and short focal lengths should be avoided.

Low-number aperture settings with shallow depths of field should not be used.

Altered photographs should not be submitted for publication or presentation unless they are explicitly labeled as such.

When consulting with patients and using morphing software, the surgeon should be conservative, taking care not to alter images beyond his or her surgical capabilities.

The advent of digital imaging and morphing software that can mimic postoperative results introduces new legal issues. Although we do not know of any lawsuits regarding the implied “guarantee” of an altered digital image, certainly the risk of this happening is real. If imaging is used as part of patient consultation, it is imperative to ensure that the patient understands that digital imaging only represents a “possible” outcome and is not a guarantee. Any altered images shown or given to a patient should include this statement: “THIS COMPUTER IMAGE CONSTITUTES A SIMULATION AND IS NOT A GUARANTEE OF YOUR RESULT” or a similar phrase, in capital letters on the photograph. Images of any sort that are given to patients should be authenticated with a time-date stamp or signature to ensure image legitimacy and to minimize the possibility of a patient tampering with images.

Concluding Thoughts

To practice plastic surgery is also to practice photography. As we strive to improve our skills as surgeons, we should also aspire to be good clinical photographers and apply standard techniques to the taking of photographs. We must exercise care to maintain patients’ privacy and rights and to use photography to educate our patients, our colleagues, our trainees, and ourselves.

Clinical Caveats

A comfortable, private area should be provided for all clinical photos with a dedicated imaging system.

All image data should be backed up on a regular basis.

It is essential to obtain patient consent for taking photos and using them for educational purposes.

Annotated Bibliography

Chavez AE, Dagum P, Koch RJ, et al. Legal issues of computer imaging in plastic surgery: a primer. *Plast Reconstr Surg* 100:1601-1608, 1997.

This article includes a brief review of the law regarding clinical digital photography. The lead author is a graduate of the Stanford Law School. The authors state that to date no cases regarding computer imaging exist in federal or state case law. Sound recommendations are made to reduce legal susceptibility when using digital photography.

Galdino GM, Vogel JE, Vander Kolk CA. Standardizing digital photography: it's not all in the eye of the beholder. *Plast Reconstr Surg* 108:1334-1344, 2001.

These authors have written multiple publications on clinical photography. This article compares clinical photos taken with different digital cameras with different resolutions. Sound guidelines regarding the standards of clinical photography are reviewed.

Milburn K. *Digital Photography Bible*. Chicago: IDG Books, 2000.

This is a comprehensive guide to digital photography that reviews the needs of a digital studio. It covers digital cameras, scanners, and image processing. This is an excellent resource for the serious amateur or professional photographer. The section on processing and editing digital photographs is extensive.

Photographic Standards in Plastic Surgery. Plastic Surgery Educational Foundation Clinical Photography Committee.

This pamphlet is a quick guide to the standards of patient positioning and camera settings in clinical photography. It is a must-read for anyone learning the standards of plastic surgery photography and handy to keep in a studio.

CHAPTER 6

The Practice:

Models, Management, and Marketing

FOAD NAHAI, GUSTAVO A. COLON, WENDY LEWIS,
MARIE CZENKO KUECHEL, ANDREW R. BERGER

The Environment

FOAD NAHAI

In today's competitive environment, practicing good medicine is only one of the talents that a successful aesthetic surgeon must possess. Business, financial, and marketing acumen, communication and organizational skills, office planning and decorating expertise, website and social media marketing knowledge, and myriad other skills or information may be required for a practice to not only run smoothly and effectively, but also to be a successful financial endeavor. These are not things we learned in medical school or during residency. With the rapidly changing face of medicine, we have to take a far more active role in understanding and directing the business and planning aspects of our practices, in addition to the purely medical and surgical aspects of providing our patients with the finest care possible.

This chapter and the three that follow cover a spectrum of issues and basic decisions associated with running an aesthetic surgery practice and offer solutions that have worked in the real world. The topics addressed range from decisions about the basic practice model (whether an academic or a private practice), management issues, patient relations, financial and budgetary considerations, communication skills, staffing and services, marketing and practice enhancement, online tools for practice enhancement, and legal considerations.

The Practice Model

There are a number of highly successful aesthetic surgeons flourishing in a variety of practice models, so it is clear that there is no one formula for success. It cannot be stated categorically that an aesthetic practice does not belong in a university setting or that the only way to have control is to be in a solo practice. Having said this, each of these practice models—university setting, private practice, group or solo practice—will affect the surgeon and the patient. The surgeon's working environment, control of everyday decisions, financial independence, and schedule flexibility are a direct reflection of the practice model. Similarly, and perhaps of greater importance, the practice model will also have a profound impact on the patient's experience.

Many renowned university programs attract patients from all over the world because of their reputation, the prestige of the institution, and the well-founded assumption that only the finest of physicians would be on staff. Equally, there are outstanding physicians in private practice whose rise to prominence has not occurred under the umbrella of a prestigious institution but through outstanding performance. This is

true in all areas of medicine, including aesthetic surgery. Many patients will place their trust in plastic surgeons on staff at the academic centers merely because these surgeons are at that center. In the private setting it is the surgeon's reputation and standing in the medical community, rather than institutional affiliation, that is important.

Traditionally in plastic surgery, it was common for young plastic surgeons, whether in private practice or academics, to start with a combined reconstructive and aesthetic practice, far more reconstructive than aesthetic, with much emergency work and cases referred or handed down by senior colleagues. As the young surgeon became established, the practice would grow in one direction or another and over the years, those of us with a special interest in aesthetic surgery would slowly build our aesthetic practices so that eventually we could limit our practice to aesthetic surgery, passing on to junior partners and colleagues the nonaesthetic part of our practices.

This model worked well for many of us who currently enjoy a sizable aesthetic surgery practice. However, this model may not work as well today, because we now practice in a very competitive environment with competition not only from our plastic surgery colleagues, but also from other core physicians and surgeons, those who are not surgical specialists, and even individuals who are not medical practitioners. The young plastic surgeon entering practice today who wants to focus on aesthetic surgery has to plan a specific course to attain those goals. Times have changed and one can no longer start a practice, cover the entire field, and expect one day to have built sufficient volume of aesthetic surgery patients to shift focus in that direction. The good news is that even though the field is highly competitive, demand for aesthetic procedures continues to grow. With this continued growth and the explosion of information via the Internet, a patient seeking aesthetic enhancements will be far better informed, more focused, and more demanding.

Each of us will have to weigh our options so we can choose the practice model that will afford us the opportunity to build and maintain an aesthetic practice in an environment in which both patients and the surgeon are satisfied.

Reflections on My Experience

Having practiced aesthetic surgery for a number of years in a university setting and now in a private group practice, I have spent many hours ruminating about these practice models and their potential impact on the total patient experience, the practice environment, and the surgeon's flexibility, professional fulfillment, and career satisfaction.

Early in my career, patients chose me for their aesthetic surgery because of my position in a prestigious academic institution, with referrals from within the clinic as well as from outside physicians. There is no question that such referrals composed the initial building blocks of my aesthetic practice. Over the years, the focus of referrals shifted from physician referrals to word-of-mouth referrals based on patient satisfaction. Today most of my patients are self-referred or come because of recommendations from friends or family, and because I now have a recognized name within the community. Although I still see physician-referred patients, even from prestigious academic centers, these constitute a small portion of my current practice.

As my aesthetic practice began to grow, it became obvious to me that my patients were selecting a surgeon who they felt would, in all likelihood, deliver the results they were looking for. However, I also came to realize that a good result was only part of the equation; it was the total experience that mattered most. By *total experience* I mean the patient's encounters with all aspects of the practice: the medical and nonmedical staff, the physical and human environment, the ambiance, and personal interactions. In today's competitive environment, the total experience may be just as important to some as the quality of the result.

Leaving the university for private practice had a significant impact on me personally and on the experience that I could offer to my patients. When I was at the university, new aesthetic patients were processed with all other new patients, often by clerks with little if any knowledge of aesthetic surgery and no personal interest in the patient or my practice. Following the initial processing, patients would proceed to a waiting room that was shared with our reconstructive patients and, for a while, with neurosurgical patients. Such an environment was not conducive to providing patients with a feeling of privacy, warmth, or nurturing. By contrast, in a private group practice focused on aesthetic surgery, those factors that adversely affected the patient's experience in the university setting have now been eliminated. Patients benefit from an environment in which everyone is focused on their particular needs. I think that all of these changes are a direct result of the degree of control that my partners and I have over the environment within our practice and the training of our staff.

In the more personal environment of a private group practice, the patient is more likely to build a relationship that goes beyond the surgeon and extends to the staff as well. This improved relationship has been reinforced for me on numerous occasions by my long-time patients who followed me from the university into private practice. They have been very complimentary about the change, specifically mentioning that they prefer this smaller, more personal and private environment.

The change in my practice setting has also had a profound impact on me. I now have full control over every aspect of my practice, including finances, office hours, and operating room access, to name but a few.

It is encouraging to note that as cosmetic medicine and aesthetic surgery have become more competitive, with patients now expecting more personal attention, forward-looking universities have developed cosmetic medicine/aesthetic surgery centers to provide the same patient experiences that are available in the community. This is a good strategy, because it makes the university-based aesthetic surgeon competitive, increases revenue, and may well contribute to retention of faculty.

As surgeons, we are in control when we are in the operating room. There isn't one of us who has not been frustrated by events in and out of the operating room that are beyond our control. In the university setting and in some group practices, there is a hierarchical structure. In solo practice there is no such structure, and this is probably a mixed blessing. The surgeon is in full command, but also has to individually deal with all contingencies. In the university, although I enjoyed a close personal relationship with my partners within the section of plastic surgery, the hierarchy went from my section chief to the department chair, to the dean of the medical school, to the vice president for medical affairs, and ultimately to the university president. Each of these individuals likely had more control over my finances and practice environment than I did. Each had his own opinions and priorities as to what was best for the university, the medical school, the department of surgery, and even the section of plastic surgery. These views often did not coincide with my priorities and did not place the pampering and nurturing of my aesthetic patients first.

I would be remiss if I did not acknowledge that despite my lack of control over the university environment, for many years I was able to flourish and develop as a surgeon within it and to provide excellent medical care to all of my patients. Furthermore, there is no question that as a young surgeon starting out, this environment provided me with an excellent opportunity for building a practice, and my colleagues and partners were highly supportive of my activities and growth.

As the focus of my practice shifted from reconstructive to aesthetic, from patients who needed and benefited tremendously from a first-class tertiary referral center to those who sought a more private, personal setting, I realized that at the university I was not in a position to change my environment or theirs. This is in clear contrast to my current private group practice setting, where my partners and I can make any change in our environment rapidly and efficiently.

One of the most rewarding aspects of my career has been the opportunity to work side-by-side with some of the brightest young minds in our specialty. Of course, I am referring to the many residents I have had the privilege of training and working with who have become leaders in our field. Over the years, only one or two of my reconstructive patients have ever inquired who would be doing their operation. The same cannot be said of my aesthetic patients, who even to this day in private practice will ask me who will operate on them. The answer then and now is that I do all my own operations and make all the decisions, but I will have an assistant. The question of resident involvement in performing aesthetic surgery is not new; the debate will continue, and I do not have the answers. There is no question that we are responsible for training the next generation of aesthetic surgeons, but we also have a responsibility to our patients and their privacy. Even though we currently have a fellow and a resident whom we teach in our practice, this is a far cry from the university setting, with numerous residents not only in plastic surgery but in anesthesia and other specialties, not to mention the medical students our patients are exposed to. The presence of such trainees is sometimes of concern to our patients. I have learned that a discussion of the role of trainees and their involvement in patient care—specifically their role, if any, in the operating room—is essential to gain patient confidence and to provide the peace of mind that the surgeon he or she has selected will in fact perform the procedure. I will always inform my patients and seek their permission to have anyone other than our full-time office-based surgicenter staff present in the operating room.

We are very fortunate in our group practice to have our own in-house American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF)-approved, state-inspected surgical facility. Although there are pros and cons to owning such centers, the greatest advantage, again, is control—control over when I start to operate, when I finish, how many cases a day I schedule, and which days of the week I operate. I had no such control at the university, other than blocked time. This flexibility, in my opinion, far outweighs any of the disadvantages of owning a surgicenter.

A few words about group versus solo practice: I have never been in a solo practice; I have always been in a group, at one time with as many as six partners. There is no question that in a group, *control is shared*. One partner is the administrator who deals with the day-to-day problems and headaches and makes most of the decisions; major decisions are made by the group. This may vary from practice to practice. In solo practice the surgeon/proprietor has full control but also has the full weight of all decision-making and financial burdens.

In a group practice, we consult each other concerning patient management, and it is most reassuring to be able to call your partner to consult about a problem. In solo practice, although colleagues may be only a phone call away, it is not the same.

Another issue is coverage. We gladly take calls for each other and take care of each other's patients in an emergency. This allows us schedule flexibility and the opportunity to travel and time for professional activities, knowing that our partners will provide excellent care to our patients during our absence.

Business and Financial Strategies

Although many of us would prefer to focus our attention on the surgical and patient care aspects of practice and leave the business and finance to someone else, that is not realistic in today's health care environment. To run a successful practice, a surgeon must have a basic understanding of the business aspects of day-to-day operations and a budget and plan for reaching the goals to drive the practice. Although it is essential to have expert accounting and other business advisors to run the numbers and execute strategic and financial plans, the surgeon needs a working knowledge of these matters to ensure that the practice runs profitably and effectively and that he or she understands the business aspects of daily operations. (See Chapter 7 for detailed information on financial planning.)

Managing the Office

Delineation of Responsibilities

Tempting as it might be for the surgeon to run his or her own office, it is money well spent to hire an office manager. A well-qualified office manager is an asset in either a solo or group practice. Although a solo practice may "get away" with the surgeon managing it all, it is more difficult and far less practical to try to do this in a group practice.

The practice manager is responsible for the day-to-day running of the practice, including collection and posting of fees, managing the staff, and other duties and must be empowered by you to do so.

In our practice, my assistant/patient coordinator meets with all new patients and is responsible for scheduling them. They will contact her for any changes in schedule and related questions. The office manager and administrative partner are responsible for hiring and firing and other personnel matters.

Relationships With Staff

We are all busy, and the last thing any of us needs is more meetings. However, an essential element in the success of any endeavor is communication. Although individuals within the practice communicate with each other daily, it is essential that the entire practice and smaller groups within the practice meet on a regular basis. In our practice, we regularly schedule the following meetings and have found them to be a most effective means of communication.

Doctors' meetings, which include the partners and the office manager, the anesthesiologists, and the manager of the surgicenter

Staff meetings, including all doctors and the entire staff

Administrative meetings, including all secretaries, administrative assistants, receptionists, and the office manager

Nurses' meetings, which include nurses, operating room staff, and the office manager

It is very important for the staff, especially any newcomers, to be familiar with your practice philosophy. We make all of our staff aware that our practice philosophy is to provide the best and safest medical care to our patients in a warm, friendly, caring environment. The patient's privacy is of utmost importance, and all staff members are aware that they may not discuss any of the patients outside the office environment. We emphasize the role that each of them plays in the maintenance of such an environment. We have monthly staff meetings with an agenda covering various topics ranging from employee benefits to compliments from patients, expansion plans, and other matters. We have found that these monthly meetings where all staff and doctors are present are essential to maintaining a close working relationship with our staff. This nurtures a sense of teamwork and emphasizes the important role they play in the success of the practice.

Training and Telephone Protocols

The first contact any new patient has with your office is through the telephone or your website. Contacts through the website are necessarily impersonal. Your telephone operator or receptionist is often the very first direct contact the patient will have with your office. The receptionist will make the first impression on your prospective new patient. It is important that calls be answered in a timely fashion by someone with a pleasant voice announcing the name of your practice, followed by the telephone operator's name and the question, "How may I help you?" The receptionist should avoid picking up the phone, announcing the name of the practice, and immediately asking the patient to hold. The one thing more annoying than this is an automated telephone answering system by which the patient is invited to respond to a number of options. We are in a service industry; our patients expect the best and there is no substitute for a kind, warm human being on the phone rather than an

impersonal machine that takes the caller through multiple options, then a selection must be made immediately or the call disconnects. Although such automated systems are promoted to save money, in the long run it is a far better investment to have a knowledgeable, well-spoken receptionist answer the telephone. The cost savings may not be real if patients hang up or are left with a poor first impression of your office and do not schedule a consultation based on this initial encounter.

The training of the telephone operator and receptionist is very important. This is usually the responsibility of the office manager, or outside consultants can be brought in to train the staff in customer service. Remember that you and your partners set the tone of the practice. Your staff will see how you interact with your patients, and it will affect their interactions.

Dress Code

Professional demeanor and dress are essential. Your practice should have a dress code policy. Patients expect a certain standard from their physicians and staff. A well-dressed, well-groomed staff reflect favorably on the practice. Extremes of fashion should not be worn; an outfit that looks spectacular as evening wear is not appropriate in the reception area. The dress code will obviously vary from practice to practice, depending on your practice philosophy and the patient mix. All staff should wear tags indicating their names and job titles/positions, and nurses and physician assistants should wear lab coats and name tags identifying them.

Office Design and Flow

The office should be arranged in such a way that the patient arrives, checks in, sits in the waiting room, is brought back to the examination or treatment rooms, and from there can go to video imaging, scheduling, and eventually check out, pay, and make another appointment, all without having to retrace and retrack.

If possible, space and expense permitting, the ideal is to have two separate waiting rooms so that immediate postoperative patients with facial dressings and those recovering from peels or resurfacing do not share the same waiting room with new patients. The immediate postoperative patient needs privacy and is better served by seating in a small private waiting room where he or she is the only occupant. Likewise, it is best not to expose new patients to this view of an immediate postoperative patient before you have had a chance to discuss the procedure and the process of recovery involved.

The second, more private waiting room is also useful for patients who would prefer not to be in a “public” waiting room. This may include individuals with celebrity status and others who desire a greater degree of privacy.

Advertising and Practice Promotion

When I started in practice, advertising by physicians was unheard of. All of that changed in the 1980s when the Federal Trade Commission (FTC) allowed advertising by physicians. As the late Dr. Michael Lewin put it in 1983, “There was an outpouring of originality, misrepresentation, and sleaze.” In the quarter-century since then, very little has changed; we continue to see false and misleading advertising, not just by physicians but by some manufacturers as well.

Despite these drawbacks, which reflect human shortcomings, advertising is a fact of life for physicians and is here to stay. In addition, the advent of the Internet and the new social media, such as blogs, LinkedIn, Facebook, and Twitter, have taken electronic connections to the next level and forced surgeons to embrace this new paradigm. Physician advertising is poorly regulated. The most stringent guidelines are those set out by professional societies which hold their members to very high standards in their advertising and web presence. A few states have passed laws that affect physician advertising. Two excellent examples are the California law that requires physicians who claim “board certification” in their advertising to mention the particular board and the Florida law, Truth in Medical Education (TIME), which requires that providers indicate—orally, in writing, or on their name tag—whether they are physicians, physician assistants, or nurses.

Community Outreach

My late partner, John Bostwick III, was a true master of marketing through community outreach. As a man of enormous charm and intelligence, he always understood, even when he was new to practice, that one of the best ways to attract patients is to become involved and to make yourself available as a speaker and educator, as a source of information for possible referring surgeons, as an advisor to support groups, and as a local authority. John always made time for these activities, no matter how busy he was. When one of the general surgeons at Emory University Hospital had a patient who wanted to speak with a plastic surgeon, he could always count on John. He made himself available as an advisor for local breast cancer and breast reconstruction support groups and was always ready to speak on a variety of topics, aesthetic or reconstructive, when a public forum was being held. These contacts were a ready source of referral, both from the patients who encountered him and from the surgeons and other physicians who funneled their plastic surgery referrals to him.

He also recognized the value of reaching out to referring surgeons, sending them autographed copies of his books and patient education materials to share with patients, and making sure that he maintained regular, collegial contacts with possible referring physicians in town. This served him well.

Internal Strategies for Practice Promotion

GUSTAVO A. COLON

If internal promotional programs are in place and effectively used to deputize patients, friends, relatives, and other physicians to refer to your practice, the cost of promotion to bring in new patients to the practice can be significantly diminished. At the same time, groups outside your immediate practice circle can be approached using cost-effective marketing tools other than mass-media advertising.

The best internal marketing tool is a well-trained staff. As mentioned previously, the staff person who answers your phone makes the first impression with prospective patients. As obvious as this seems, I have noticed that many physicians seem unaware of how their phone is being answered. Patients should feel that from the very first phone call their needs are your most important concern. They should also perceive that your appointment schedule and other aspects of your office management are handled in a highly efficient manner.

It is vital that all staff members who deal directly with patients be consistent in their approach; they should be adequately prepared through a comprehensive staff training program. The staff should always express your philosophy, plans, and procedures—not their own personal ideas.

The next step in creating a positive impression is the initial office visit. Office decor should be comfortable and appealing and consistent with the practice. Ostentation should be avoided, since it could have a negative psychological effect on patients, who might automatically assume they cannot afford your services. The flow of patients in and out of the office should be smooth, with prospective patients separated from current patients if at all possible. Finally, ample parking should be available in close proximity to the office.

Every surgeon occasionally has a patient who wants to argue about fees or voice other complaints; as minor as these disagreements may be, they surely would be disconcerting to new patients and should always be discussed in a private setting. Patients want their physician's office to be well organized and efficiently run for psychological reasons as well as practical ones. If the office is chaotic, patients may conclude that the surgeon's operating room is similarly haphazard.

Small touches are important. Every patient who visits our office receives a thank-you note, mailed out the next day. We also make a point of sending thank-you's to referring patients and physicians. It is also important to keep in touch with past patients, even if it is only a once-a-year mailing of a newsletter, practice brochure, or patient questionnaire. People appreciate receiving information on new techniques in aesthetic surgery or being updated on changes within your practice. If you send out any kind of literature, invest the time and money to produce an attractive and

professional-looking piece. A poorly designed newsletter or brochure will not achieve positive results for the practice. Tracking patients through a computer system should make periodic mailings a relatively easy task.

Monthly, potential new surgical patients should be tracked against new patients seen in consultation. At least once or twice a year, this ratio should be compiled and checked. If the ratio is less than 50% of new patients who actually schedule for surgery, try to find out what is happening to the rest of your prospects. Consult your records for clues. This review is likely to suggest changes you might make in your practice management and your personal style and/or your staff's approach to patients. Personal public relations should be used rather than advertising to boost your image in the community. This will keep the promotional costs down. Offer seminars on aesthetic surgery or plan an open house in the office. The staff should be adequately prepared for these kinds of professional or social interactions in or outside the office, especially if you have an office surgicenter.

In any patient contact, it is important to maintain a warm, personal manner. The patient should be shown through eye contact and a brief touch that he or she has your respect. Include in your notes personal information the patient mentions, such as a new job, an upcoming vacation, the wedding of a son or a daughter, and so on. Then the next time you see the patient, you can inquire about the vacation to Bermuda or how the new job is going. The patient will be amazed at your memory, and such inquiries will help convey your genuine interest in the patient. It is that kind of friendly professionalism that earns trust and shows that you are a caring physician.

Your patients are your most receptive audience; keep them happy and informed and focus on providing a rewarding patient experience. A professional, ethical reputation is essential; this should be reflected in your every interaction with patients, staff, and others. It has been demonstrated that a happy patient, on average, will tell three or four other prospective patients about you, but an unhappy patient will spread the bad news to 20 or more potential patients.

Patient Relations

The Role of the Physician

WENDY LEWIS

Patients need to feel that they can bond with the surgeon and have confidence that he or she can address relevant concerns and provide needed services. Because there are so many choices today among practitioners, likability is often the determining factor when patients choose you over your competitors. They want to feel a connection with their plastic surgeon. When training, expertise, reputation, results, and costs are equivalent, intuition and personal impressions will factor into their final decision.

Building trust with patients is critical to the success of an aesthetic practice. You can instill confidence through the words you choose, your tone of voice, body language, eye contact, and facial expressions. Patients want to feel special and unrushed, as if they are the only patient you have. They want and expect your full attention during every visit. As mentioned previously, your ability to remember small details about each patient will help to establish a strong bond. Whenever possible, it is important to speak in specific terms that relate to each patient, rather than in general terms that are less personal. This more personal approach shows that you have taken an interest in the patient, and that he or she is not just a number in your practice.

Steps for Building Rapport With Patients

- Smile warmly when greeting the patient and use his or her name.
- Shake hands as you meet, and establish eye contact.
- Seat yourself on the same level as the patient.
- Do not allow interruptions during the consultation.
- Inquire what the patient's particular concerns are.
- Listen carefully, without interrupting or contradicting.
- Don't fidget; remain focused on the patient.
- Jot down notes as reminders of personal details.
- Let your responses reflect that you are actively listening; repeat the patient's words back for confirmation and mutual understanding.
- Ask open-ended questions to stimulate further communication.
- Do not appear rushed or eager to conclude the meeting.

Well-informed patients can be a challenge. On the one hand, if they are knowledgeable about procedures, have done their research, are serious about proceeding, and are essentially prequalified, they can reduce your consultation time significantly. On the other hand, some patients think they are well informed but have actually received incorrect or misleading information from unreliable sources. These patients may pride themselves on being well informed, so it is wise to acknowledge their efforts. In this situation, your job and that of your staff becomes more difficult, because you will have to reeducate them. When a patient comes to a consultation with a thick file of printouts from websites, articles from magazines, and a legal pad of notes and questions, it is helpful to inquire about the sources of this research to get a sense of the quality of the information on which the patient is relying. Even if you disagree with something a patient says, you should avoid contradicting the patient; instead, diplomatically point out another way of approaching the subject without making the patient feel stupid.

Communicating

To relate to potential new patients, you need to understand how to effectively communicate with them. When people visit an aesthetic surgeon, they are often uncomfortable and unable to communicate freely. You may find yourself having to coax information out of a prospective patient. You may have to ask questions in more than one way to extract the real responses you need to determine the best treatment plan. Probing further may allow you to gain insights into who the patient is and his or her motivations.

In other cases, the patient may not stop talking long enough for you to get your points across. This may be from a combination of nervousness, excitement, and anticipation, or a sign of a controlling personality type. In this instance, it may be best for you to talk less and listen more. By paying careful attention to the subtle ways in which patients express themselves, you can pick up important clues to their personalities, fears, and possible psychological issues; this facilitates better screening.

Most surgeons start a cosmetic consultation by asking the patient to describe what his or her principal concern is. It is rarely going to be just one feature or area; rather, the patient may have a laundry list of many areas needing attention—the skin, the face, and the body. The first item mentioned usually holds particular significance. For example, if a patient opens by tugging at the slack skin under the chin and states, “I feel like I am beginning to show my age,” the lower face may be the major source of concern. Therefore, if you suggest a face lift and blepharoplasty but fail to adequately address the neck, the patient may be disappointed.

To streamline the consultation process, it is important to get the patient to focus on the problem that is most pressing. It is nearly impossible to cover multiple areas sufficiently in a single visit, especially if it is a first visit. If the patient comes in with a legal pad of questions, you may suggest that the initial consultation be divided into two sessions so there will be enough time to cover everything. The patient should be urged to prioritize—face versus body, or eyes and nose versus breasts and liposuction—so you can map out a long-term plan that is safe, sensible, and in line with the patient’s budget. Start with the first stage. If all goes well, the patient will return for other procedures or treatments over time, and you will have built a long-term relationship.

While explaining how you would address the patient’s concerns, speak clearly, keep it simple, and use straightforward, conversational speech. Avoid phrases that instill fear and anxiety or confuse the patient. For example, “discomfort” is preferable to “pain,” and “redness and bruising” will be easier to grasp than “erythema and purpura.” Provide ample opportunity for the patient to ask questions, which will allow you or your staff to go into greater detail based on the patient’s level of understanding and quest for specifics. When you feel that the consultation is coming to a logical conclusion, always ask if you have left anything out or if the patient needs more clarification.

At the close of the consultation, you'll want to reassure the patient that you have performed many of these procedures with excellent results, and that you feel confident that you can meet the patient's goals and expectations. Think empathy; convey that you understand their concerns and fears, and that you look forward to seeing them again.

Cosmetic patients expect clinical excellence. They need to know that they can expect consistent results in your practice, especially for repeat treatments. If nonsurgical procedures go well, patients are more likely to feel confident entrusting you with more invasive procedures in the future.

Today's patients will not be comfortable with being pressured into booking surgery at the first visit. You can expect that if you are the first plastic surgeon they have consulted, you will surely not be the last. The average patient today will see at least three surgeons in consultation, and often twice that, especially if free consultations are common in your geographic region. Beware of the patient who has seen an unreasonable number of doctors; this is usually a red flag that he or she is not serious, is unable to make a decision, or is unstable.

The Role of the Patient Coordinator

The clinical and nonclinical staff in your practice who deliver service play a significant role in creating the patient experience. One of the most critical roles in an aesthetic practice is that of the patient coordinator; he or she is the "go-to" person who manages the consultation process with patients. A good patient coordinator can have a profound impact on the success of a plastic surgery practice. This is the person to whom patients turn when questions arise. Patients want to feel that they are in good hands and in a safe and nurturing environment. The patient coordinator helps to achieve that goal.

A highly skilled patient coordinator who has been with the practice for many years reflects favorably on the surgeon and practice; he or she is seen as a loyal staff member who fosters a continuity of care that is comforting to repeat patients and reassuring to new patients. Frequent turnover may signal to patients that the office is disorganized and inefficient and that the doctor is difficult to work for.

The patient coordinator serves as a vital link between the surgeon and the patient. Patients often perceive this professional as more approachable than the surgeon and consequently will often be more open to confiding private information and concerns. The patient coordinator must be able to connect with patients on a personal level and to instill trust and confidence in the surgeon and the practice. The patient coordinator can promote your credentials, training, and expertise with patients much better than you can, presenting your surgical results in the most effective manner.

The patient coordinator is responsible for much of the handholding and personalized attention to detail that is provided in a well-run aesthetic practice. Communication skills are of paramount importance. This professional should be able to handle the most difficult and demanding patients with equanimity and a friendly, helpful manner, never showing annoyance or frustration. This key staff member should be nonthreatening to both male and female patients and mature enough, for example, to make perimenopausal women feel at ease in disclosing their concerns about the aging process.

In a busy aesthetic surgery practice, it is common for the patient coordinator to conduct a preliminary consultation with new patients before they meet with the doctor. This professional should be adept at establishing a bond with patients during these initial meetings that will help to guide them through the surgical process and prepare them for what to expect during the consultation, thereby saving valuable doctor-patient consultation time. An effective patient coordinator should also be attuned to the nuances of conversion. A low-key approach reviewing the merits of the procedure and highlighting the surgeon's unique capabilities is usually preferable to an overly aggressive sales pitch that can be a turn-off to many patients.

It is always preferable to assign this critical role to an individual who can make this patient interaction his or her foremost priority. A patient coordinator who is encumbered with a multitude of responsibilities cannot devote sufficient time to appropriately manage potential patients. This professional's effectiveness will be limited if he or she feels overburdened and is pulled in too many directions to give patients the individual attention they expect. It is virtually impossible to act as a true patient coordinator while having to answer the phone and schedule appointments in between explaining the complexities of a face-lift procedure. Patients also find these interruptions to be distracting and inconsiderate of their time.

The environment in which the patient coordinator works is another key consideration. To perform the job effectively, the patient coordinator should have a proper office or secluded area in which to counsel patients. Whenever possible, this office should have a door that can be closed to preserve patient privacy and create an intimate atmosphere in which patients can talk confidentially without fear of being overheard. With the current emphasis on medical privacy regulations, this type of private space should be considered mandatory. For young surgeons just starting out in practice, it may be acceptable to have an office manager or nurse handle these responsibilities during the first few years. However, as the practice grows, it is important to hire someone whose main function is to educate your patients, promote your skills, and schedule procedures.

Potential Pitfalls in the Office

- Long lead time for consultations, treatments, or surgery
- Long waits in the reception area before patients are seen
- Delays in returning phone calls
- Excessively high fees; poor value
- Doctors or staff members who appear rushed and inattentive
- Unprofessional, inattentive, or rude staff
- Poor office management
- Reluctance to show before-and-after photographs
- Reluctance to discuss training, qualifications, and board certification
- Lack of attention to details, service, and follow-up

Patient Education Tools

Before patients decide to proceed with treatment, they need confirmation that they can relate to your practice and the quality of your work and will be happy with the outcome. Educational tools are helpful in supporting your treatment recommendations and in assisting patients to visualize the range of results they can expect. Patients want to see examples of your results. These tools are also a valuable means of marketing the practice and the quality outcomes it provides.

Technology offers a number of tools for improving doctor-patient communication; these can be helpful when discussing different procedures and their associated risks, limitations, and possible outcomes. For example, digital photo albums and PowerPoint programs can be used to showcase your clinical photographs on a continuous loop, both on the practice website and in the waiting room. Some practices have invested in touch-screen patient education centers to highlight the procedures offered. Skin analysis systems offer another opportunity to engage patients and educate them about their skin quality and to recommend products. Most vendors provide practice marketing materials, including brochures, postcards, mailers, DVDs, media clips, and even reward programs that can be effective in attracting new patients. The addition of a sleek flat-screen monitor and a DVD player in part of your reception room can transform this area into a patient education center.

Patients have come to expect some form of computer imaging in a modern aesthetic practice. They want to see simulated results to help them decide whether this is the right surgeon to meet their needs. Computer imaging is an effective communication tool during the consultation and when reviewing surgical results. It provides a basis for defining goals and developing an appropriate treatment plan. It also helps to rein

in patient expectations by demonstrating what is and is not possible to achieve through surgery and adjunctive treatments. When showing patients preoperative and posttreatment photos, it is important to select patients of the same sex and similar age, ethnicity, and skin type who had comparable procedures. Patients cannot be expected to imagine what their results will look like; they want the surgeon to show them what to expect.

In the age of Internet and social networks where consumers meet online to discuss their experiences, it has become commonplace for prospective patients to ask to speak to other patients. If the surgeon is unwilling to have satisfied patients serve as a reference, then staff members who have undergone treatment are a good alternative.

Signage within your practice is also important to educate patients about every procedure, treatment and product that the practice offers. A common lament among doctors is the long-standing patient who undergoes treatment somewhere else and proclaims, “If I had known you do that, I would have asked you about it.” One way to avoid this missed opportunity is to regularly communicate with your patients through email blasts and newsletters, keep the practice website up to date, display a menu of your services in patient areas, and provide brochures on the brands featured in your office.

Office Materials

FOAD NAHAI

Today’s patients want to be as well informed as possible. They have access to a wealth of information online, some accurate and informative and some highly misleading. We have the opportunity to provide our patients with balanced information concerning aesthetic surgery. This is one of the best marketing devices we have. We have three avenues open to us for disseminating this information: our website, informational brochures, and electronic media, such as DVDs and videos. On the website, you should include a brief biography or mini-curriculum vitae of each surgeon in the practice, a statement of your practice philosophy and mission, contact information and address, maps and directions to the office, and images of the office, surgicenter, and overnight stay rooms if you have them. You should also include a list of frequently asked questions, a description of operative procedures and cosmetic treatments offered, and a gallery of preoperative and postoperative pictures.

Although most patients have access to your website and have probably visited it more than once before making the appointment to see you, it is worthwhile to mail a package of information about the practice to each new patient at the time that the initial appointment is made. In our practice, this includes a folder with several inserts including a description of the practice, a biography/mini-CV of the surgeon with whom they have made the appointment, directions to the office, and a list of local hotels

and restaurants (see Chapter 1). In addition to the information about the practice, an appropriate procedural information brochure is placed in the folder. The design of the information packet should be coordinated with the look of the website. All of this information should also be available on your website.

During the initial consultation, most patients are shown preoperative and postoperative images of patients who have undergone similar procedures. It is a good idea to offer patients the opportunity to view an informative patient education video or DVD of the procedure they are interested in. For patients who will have implants, an additional informational booklet is provided. For patients undergoing Botox or Restylane injections, the manufacturer's brochure is also helpful.

An effective internal marketing approach is to have a variety of brochures about procedures available in your waiting and examining rooms. A patient who is seeing you in consultation for a face lift may not be aware that you or others in your practice also perform breast and body-contouring procedures.

MARKETING AND COMMUNICATION INITIATIVES

MARIE CZENKO KUECHEL

Making a Connection

The very last thing that many aesthetic surgery providers manage in their practices is the very first thing your patients will encounter—not your staff, services, or fees, but your marketing and communications. Most people acquire information about aesthetic surgery from television, magazines, the Internet, or other people; however, this is not always how they locate a provider. Where individuals connect with a provider varies widely; it can be through referral by a physician, friend, or family member, through an Internet listing, or an advertisement.

The best way to manage the messages that influence your patients' decisions is through strategically targeted communications that make a connection that yields the right results. Every connection you make can enhance your practice's ability to thrive. Making a connection requires:

- A goal that defines what you hope to accomplish by making a connection
- Effective and appropriate vehicles for delivering your message
- A call to action that motivates others to act
- A cost analysis of these communications (worth as well as expense) to maximize their value

The most successful practices establish a connection, maintain it at every opportunity, and communicate effectively. This is neither marketing nor advertising. Marketing encompasses all the activities necessary to get others to accept or purchase your services or products. Advertising is a marketing strategy—a paid message about a service or product for sale. Many successful aesthetic practices do not advertise, but every practice must market, persuading others to accept or buy into their services. Marketing is essential for effectively communicating your practice's identity, for getting others interested in the services you provide, and for enabling potential clients to connect with you. You must convey how and why you can best fulfill the patient's desire for appearance enhancement and extend the invitation to act on this relationship. Communication and education are part of the marketing mix and are intricately intertwined: without one, the other is useless.

In an aesthetic surgery practice, education is the basis of every message. Regardless of your audience, you need to communicate essential information about the services you provide and your ability to provide them. The way in which a message is delivered to your intended audience represents half of its value. This can be done with varying levels of efficiency, speed, attraction, and cost.

Although patients are usually the focus of your marketing and communication strategies, it is also wise to target some of these communications to referral sources and business-to-business resources to enhance your ability to attract new patients.

Marketing Channels

There are three general communication initiatives essential to every practice of aesthetic medicine: patient relations, outreach, and advertising. Even if you have the skills to provide services and have willing patients who desire your services, your practice will need to communicate through one of the following marketing channels:

1. **Direct communication:** Specific messages designed for visibility and education, to retain current patients, to encourage service and repeat service, and to elicit referrals. An example is the patient education or core practice materials that you put into your patients' hands or make available in your practice setting.
2. **Outreach:** Outreach entails no-cost or low-cost messages to your target population that provide visibility, education, and generate traffic. Examples include your practice's website, your referral sources, *social media* (such as blogs, Twitter, and Facebook), and one-to-one networking.
3. **Advertising:** Ads are created specifically to reach the market of individuals interested in your services or those in a specific demographic. Ads provide vis-

ibility and education and generate traffic, but there is a fee for their transmission. (Examples include directories, magazine or newspaper ads, the recorded message on your telephone hold system, and even articles you pay to have placed.)

Marketing and Communication Goals

Goals must define a target and an endpoint, something that signals that you have accomplished your goal. Look carefully at the messages and tools you use to connect with your market, community, peers, patients, and staff. Goals for your marketing and communications include the following:

Visibility: Your practice must be visible to those with whom you need to communicate. Make certain your message is consistent with the image you want to project.

Announcement: Announcements should be made when there is something important to convey, such as a new location, a new staff member; different hours, added services, new policies, or rebuttals to misinformation by the media. Don't announce something dated or trivial, and don't attempt to impress your audience with something you cannot substantiate. For example, don't claim to be the leading provider of a cosmetic injection or to have some innovative technique with injections unless you can support this claim.

Solicitation: The service or a product you sell is part of your business and your success. Sharing your service menu on a website or with referring physicians is an example of solicitation.

Education: Every communication should educate, directly or indirectly. If you don't have at least one key piece of valuable information to share, remain silent. Explaining your service menu to staff, referral sources, prospective clients, and peers is part of this education process.

News: News is timely, previously unreported, important information that is of interest to others. It is not self-serving. If you have valuable news, share it.

Novelty: A novelty is something new and fresh. If your goals for connecting are based on novelty, be certain that you are well informed about what that novelty can accomplish. You may be excited about a new procedure, product, or device, but before you promote it, make certain that it holds promise for the long term. You may wish to be known as a trendsetter, but be certain you are backing the right trend.

Compliance: You need to communicate to current and prospective patients that you comply with the highest standards of care and ethics in your specialty, whether with CME or accreditation of facilities.

Pressure: The only appropriate pressure would relate to a clinical matter that affects a patient's outcome or health. Pressure to act now because of pricing or novelty creates a false connection and will result in a failed relationship.

Price: Your services have a valid cost. Connecting with a potential patient on price is valid only when you know specifically what is desired and appropriate for the individual.

Connection: You must develop marketing strategies to help you maintain your connection to others. Connections can come in the form of an invitation, a personal message, a reminder, or simply a communication that maintains your visibility for your patients, referral sources, or the community.

Call to Action Essentials

In marketing strategy, a *call to action* is the response that your communication is intended to elicit in specific groups. Much like the practitioner who does not ask for referrals, a practitioner who does not extend a call to action is not likely to receive a reply.

Your audience at large: In communications that generate interest and visibility, the objective is traffic, conversion, and retention. Your call to action may be as simple as letting people know where they can find you, or as direct as an invitation or query about an individual's desire for services. The call to action must be clear, timely, and effective and must not invade privacy or violate good judgment.

Prospective and current patients: The best calls to action allow individuals to act on their own time, in their own fashion, with no deadline, money, or personal pressure attached. Consumers today are savvy about what they want and are aware of attempts to elicit a response from them. Use this to your advantage by producing a message that is educational but also speaks to patients' personal desires. In this way you will create a call to action that fits your audience.

Patients and referral sources: To generate added business, your call to action for patients and referral sources should be direct. The purpose of your communication requires that you ask for referrals, so the call to action should provide the information and motivation necessary for the referral source to act. Ongoing patient education and outreach through newsletters, clinical updates, and special offers must include valuable information about what you want others to act on; the inclusion of an incentive is added motivation for the individual being referred.

There is a difference between incentive and gratitude. *Quid pro quo* (something for something), such as a gift or bonus for a referral, is unethical in the realm of medical treatment, much less elective medical treatment. Gratitude, not incentive, is essential. Gratitude acknowledges that you are aware of an individual's effort on your behalf and in turn, your gratitude fuels future referrals.

Your call to action with referral sources must make it easy for a referral to come to you. Establishing relationships with referring physicians is essential to your practice's success. These referral sources need to be your partners in patient care; therefore you should keep them informed as well as support their status as providers to that patient.

Beneficial referral relationships are sustained with efficient communication. Provide practice materials to those who refer patients to you, and don't forget to keep them updated any time you have new information to offer.

Business to business: Whether you are dealing with a commercial advertiser, a pharmaceutical vendor, or even a professional society, your call to action requires that you state your expectations, why this organization has value to you, and how you intend to be of value in return. Your value in return is not just revenue; it is exposure, loyalty, and active participation in upholding standards in your profession and defining trends.

Inside-Out

Outside your practice, you attempt to attract the attention of others so you can establish a connection. Inside your office, you have made the connection of interest; now you must ensure that it translates into service delivered and loyalty generated. The vehicle you use to communicate with your patients, staff, and those who are regularly in your office is not as important as how you use it.

Interpersonal communication: Interpersonal communication is the vehicle of communication that exists solely within your practice and is your most effective communication vehicle. It delivers your message directly to an individual and allows him or her to respond directly. Interpersonal communication within your practice need not be the sole responsibility of one person. As long as the lines and responsibilities of communication are clear, interpersonal communication should be a team effort.

Telephone: As discussed earlier, telephone communications are key to your practice. Next to interpersonal, in-person communications, your office will communicate most frequently by telephone, so this tool must be used effectively. You should call only where you have permission to call (the patient has indicated that he or she may be contacted by phone). When making calls, always greet the person and ask if the timing of the call is convenient. Be prepared with all necessary information and questions. Deliver your message and then determine whether the recipient of your call has questions, concerns, or comments. Look for closure, even though you are the one who made the call. Even if the call is simply an appointment reminder, make certain the patient knows when and where to arrive, what to expect, and that you are looking

forward to welcoming him or her. Automated appointment reminders may save you time and money, but they are impersonal and uninviting. It would be better to text or email the patient than to do this. (See Chapter 1 for more information on interpersonal communication and telephone etiquette.)

Email: Email is an effective means of communication when it is welcomed, informative, and personal. Email that is overused will be ignored. When your office emails people for multiple purposes, be certain you have a distinct sending address for personal patient email, one for general messages and one for business. Email may be quick, but it need not be impersonal, and it must not be impolite. Sensitive information or information specific to an individual's course of treatment should not be conveyed in emails; it is better left to a telephone conversation for privacy.

Today email is best used for administrative tasks, such as collecting and sharing information or documents. It is effective for appoint reminders or for delivering instructions. Email is also an excellent method for sending targeted messages from your practice, such as an invitation to a special event, a new product in stock, or simply to fill appointment slots that are open.

Voice mail: If you must leave a message, ask that the intended recipient return your call; never offer detail, because you cannot know who will listen to the message. Avoid an exchange of voice mail questions and answers. Set up a convenient time for a phone conversation or an in-person appointment. If it becomes too difficult for patients to connect with you, they might just disconnect the relationship. Define a policy for the office's voice mail; require that it be checked regularly and ensure that every call is answered the same day.

Text and instant messaging: Although text messaging has become popular and many use it in the same manner as email, do not view it as equivalent to email. If your patient or those you are communicating with have indicated that they are open to accepting text messages, keep these communications short and simple, such as appointment reminders.

Print: Printed materials remain an essential part of any practice. A print document may be easier to view; it can be transferred electronically as a PDF or by hand. A handwritten note is still the most gracious way to say "thank you." Some communications, such as congratulating a patient on an exciting life event or achievement or expressing sympathy at a loss, should only be sent as a handwritten personal note. Such courtesies should not be lost in the rush of daily communications; the personal touch will have deep meaning for the recipient. This is a part of building and maintaining an ongoing relationship with a valued patient.

Computer: PowerPoint, computer animation programs, and other automated functions can be used to educate and communicate with patients. These may support or enhance interpersonal communication and education, but they cannot replace them, nor are they the primary means of communicating. *You are in a personal services industry, so it is vital to keep it personal.*

Multimedia: Whether you use computer messages or play video messages of interest in your office, don't allow multimedia to dominate the environment or replace the personal connection, or you will simply lose your connection with your patients.

Display: Various items will be displayed in your office, such as skin care samples, tabletop posters, even the syringe tray setup on the examination room counter. Carefully consider which items to display and where to place them. Avoid clutter—too many diverse or unrelated displays are distracting to patients.

Connections With Your Patients

There are specific kinds of connections that only you (or you in association with key staff members) will make with your patients. These include the consultation, physical examination, patient evaluation, discussion of treatment options, treatment planning, education about treatments, photography, patient instructions, and patient consents. How you conduct these basic functions will have a direct impact on the success of future interactions with your patients and your ability to convert them or retain them.

Treatments and follow-up functions can seem routine, but they are an important means of relating to your patients.

Treatment: Until your patient accepts treatment, you will make numerous connections for multiple reasons, all culminating in treatment. Whether the process takes a few moments, several visits, several weeks, or even months of consideration and time, treatment is the goal. All of the basics for connecting in your practice—environment, greeting, function, administration, and closure—must be conveyed with the same care throughout the patient's experience. Your goal is not to make the connection for this treatment alone; you are striving to satisfy the patient's desires and make the entire experience satisfactory.

Follow-up: After treatment, three things seem to happen: (1) patients follow procedures for a necessary visit, such as suture removal, or (2) they return when something just isn't right, and (3) sometimes they revisit the practice when they desire additional treatment. Some practices suggest a follow-up timetable, but they don't insist on it or schedule it—they wait to hear from patients. Proactive practices employ one of the many communication tools available to stay in contact with patients and to follow up regularly. Whatever your method of maintaining contact, follow-up must not simply be a rote post-treatment necessity or a means of addressing complications. Meaningful, productive follow-up is a matter of good practice.

Managing or exceeding expectations does not result from a single marketing strategy or any single connection you make with your patient; it results from the numerous connections you make inside your office, using multiple communication vehicles to achieve a satisfied and loyal patient.

Connections With Referral Sources

Within your practice, it is essential to connect with the people who are your sources for referral and help you to grow your practice. Patients who refer others to you will also return as patients themselves or will accompany their friends. You may see them on social occasions hosted by your practice, or you may reach out to them regularly to express gratitude and personally acknowledge their importance to your practice. Other physicians, service providers, or your direct peers who refer patients to you may connect with your office to refer, confer, learn, or observe. Invite them in, keep them connected, and in turn they will continue to connect others to you. There are important strategies for managing your referral sources, and keeping them connected inside your practice.

Remain personally connected: Remind others that you appreciate them as individuals, that they are important to you and are not just referral sources. Greetings on the anniversary date of a major procedure, annual follow-up calls, or a personal note any time will be welcomed.

Remain clinically connected: Keep your sources abreast of new developments in your practice or specialty regarding what is relevant to them or to the patients they refer to you. Rather than simply putting this in writing, invite them in for a luncheon, seminar, treatment, or to observe. Keep them educated, and they will keep others educated about you.

Show gratitude: The most common reason for a disconnect with your sources, next to arrogance, is failure to show your appreciation. If you cannot say thank you, don't expect future referrals.

Referral sources grow your practice from the inside-out, so keep them inside in as many unobtrusive, personal, and appropriate ways that you can, manage your relationship with them, and the expectations you have for that relationship.

Business-to-Business Connections

Inside your practice you need to connect with and manage relationships and expectations with sales, service, and patient resources—those whose businesses or products support your practice or who want your support in their endeavors. These business-to-business resources can be the most overlooked connections inside the office, simply because they are more often viewed as “selling” rather than “servicing.” When

connecting with resources, you certainly don't want to tax your valuable time, nor do you want to miss out on valuable opportunities:

Screen and team: Screen all visits and functions for resources carefully before agreeing to a meeting; make certain the time is well spent for both sides. Assign a team member to manage the relationship, review new products, data, research, procedures, or services, and provide you with the most pertinent information so that you can make a reasoned decision.

Pay attention: If you have only 10 minutes to meet, give that resource person your full attention during that time. If you are not willing to devote time to this individual, have a team member screen and report back to you; be sure that team member follows up with the resource, because you never know when you might need the one person you've been avoiding.

Ask for data and analysis: Resources often come to you with an opportunity. Expect and request data and analysis that show whether that opportunity would be attractive to your practice. In doing so, your resource has the opportunity to connect, and you have the opportunity and the information to make an objective judgment.

Outside-In

The most commonly identified marketing strategies are those that reach individuals outside your practice and bring them in. Connecting from the outside-in is a more complex process today than ever before. As author David Shenk noted in *Data Smog*, a marketing publication, the average American encountered 560 daily advertising messages in 1971, which rose to more than 3000 messages per day by 1997. Today various groups, from Nielsen to the Magazine Publishers of America, report that the average American may now be receiving as many as 6000 daily commercial messages—a truly overwhelming number. As a result, your marketing strategies must be more targeted than ever. Four distinct strategies—advertising, outreach, directories and media relations—must be engaged to create and maintain visibility, generate traffic, educate others, and invite those on the outside to come in.

Advertising

Advertising is a form of communication that maintains your visibility to an outside audience. This is a controlled communication that is an extension of your practice in which you have total command of the goals, message, tone, and call to action to be conveyed. Advertising messages can be disseminated through a number of vehicles, ranging from print (billboards, newspaper, magazines, directories, and direct mail) to electronic media (radio, television, the Internet, and other electronic delivery channels).

Advertising can be general and serve the simplest and most far-reaching goal: visibility. It can also deliver a targeted message to an audience that is potentially interested in and responsive to your services. Knowing your audience and its potential response is of primary importance when choosing the right vehicle to deliver your message. This vehicle must be based on the demographic segment it targets and the potential effectiveness of this message once conveyed. The need for creating and delivering paid messages and for measuring their impact on your practice is fundamental. Every advertising plan should be monitored and evaluated continuously throughout its execution. Strategies that do not work can be modified. If you fail to reach your intended audience, reexamine their demographic viability and interest and reevaluate the vehicles used. Messages that miss the mark must be redefined.

Advertising Essentials

Advertising is the marketing strategy that most succinctly characterizes you and your practice to the people with whom you have the least personal connection. Any successful advertisement must:

- Address a specific goal: visibility, announcement, solicitation, education, news, novelty, or compliance. Pressure tactics and price do not belong in advertisements for medical services. Define your goals so that you can measure the success of this connection.

- Call attention by making a visual and/or verbal connection to the audience (headline). Who does this message need to positively attract?

- Clearly communicate your purpose, which may be as simple as visibility, or as complex as announcing a new service (body). Use a tone that is attractive, inviting, and familiar (words, images, colors). What is your message designed to convey or accomplish, and to whom is it directed?

- Directly and clearly issue a call to action related to your purpose (how, where, and why others should reply). Determine how you want others to respond to this message.

- Tie all elements together concisely and consistently.

Whether you develop ads on your own, hire a professional agency, or allow the channel through which you advertise to craft your message, you must micromanage how you, your practice, and your message are represented:

- Any paid message must be detailed and precise in its imagery and language. To someone who does not know you, this introduction should convey professionalism. To those who do know you, it should be consistent with the professionalism they have grown to expect.

- No aesthetic surgeon should allow any paid message to be disseminated without personally reviewing the message first and feeling fully confident that it is representative of his or her image and practice. Trust your intuition and judgment if you do not feel comfortable with this message. You have worked hard to build your image, and it is crucial that the message be true to your mission.

Outreach

Outreach is any event or opportunity that allows you or a representative of your practice to deliver a message of purpose. For an aesthetic surgery practice, outreach creates visibility for you and your practice at a defined time when you or your representative can personally extend your message. Through outreach, much like advertising, your practice must directly convey who you are and a concise message to a target audience. Unlike advertising, where a message is concise and controlled, through outreach, your audience and the vehicle or partner you rely on may take control of the effort. The vehicles for your outreach strategies are among the most varied, from traditional means such as holding an event to the rapidly growing outreach of social media.

Like advertising, outreach can put you in touch with prospective and existing patients. Outreach strategies individualized to your practice and focused on a specific audience are often overlooked, despite the immense value they have to your practice for renewing communications with inactive patients to remind them about your services, or for referrals, or to maintain visibility. You have to reach out beyond your practice to keep people coming in. Who better to reach out to than those who already have an established relationship with you? Some outreach efforts can be golden opportunities to put you in the spotlight for individuals who are interested in your services but are not yet ready to make an appointment for a consultation.

Beware of participating passively in an outreach effort that is shared or driven by another group; make certain your image and message can be delivered in a predictable manner with a set agenda. Participate in planning and carrying out these forms of outreach, and make certain that you know the other participants and their expectations and contributions as well as your audience's expectations. Many aesthetic surgery practices are hesitant to engage in live or social outreach because of the unpredictable return on investment and lost time away from productive practice. However, most successful practitioners recognize that if you do not reach out to those interested in your field of expertise and those in your geographic or professional community, you cannot expect that they will reach in to engage you.

You may have discounted the value of some of the new social networking channels of communication as too gimmicky for your taste, but online networking is here to stay, and your practice can capitalize on the growth of these social media. The generation who will be your target population in a few years is extremely Internet savvy, and you must be, too.

Twelve Outreach Tactics

No matter which of the many outreach strategies you employ, successful management requires that you define goals and a call to action that will bring patients into your practice.

1. ***Seminars/lectures:*** Seminars and lectures must be of interest to the intended audience. Individuals must walk away having learned something beneficial to them personally or professionally. Make certain you have a clearly defined agenda and goals for your seminar, with an organized presentation, no matter who or how many are in the audience.
2. ***Treatment events:*** Treatment events may be as intimate as prebridal party preparation, or an event that draws complete strangers to experience something new. Seminars are often combined with treatment events. Be sure that the attendees are willing to participate and that all appropriate procedures are followed, including screening of candidates, patient education, and informed consent. Before anyone is treated, regardless of the procedure, confirm that you have consent to treat and that the individual is comfortable accepting treatment in the group. I personally don't like treatment events that go beyond aesthetician services, skin care, and cosmetics. Anything more is a truly personal endeavor and should be provided in private.
3. ***Expos and trade shows:*** Trade shows and expositions can be hosted by any number of businesses, or they can be a collaborative effort arranged by a marketing company to bring together similar businesses. Expos and trade shows take time, preparation, and the right staff to interact with and educate visitors, and such events can be unpredictable. You may find yourself standing idle or be very busy interacting with attendees. It is important to know who is hosting the event, the audience who is attending, and the past history for this event. Then you can gauge your time and investment accordingly. Do not hand out samples of products unless you anticipate you will have enough and they will be appreciated; bring ample, high-quality, branded information about your practice and try to make beneficial connections. Offering things such as complimentary skin analysis will draw people who ordinarily would not partake of your services—but you must understand that it is unlikely you will ever see those people again.
4. ***Social occasions:*** Social occasions offer an excellent opportunity for networking, whether you are the host or a guest. Don't arrive at your neighbor's cocktail party and hand out business cards, but don't be shy about asking people what they do so you can share what you do. Even among people you know, social occasions are an important time to network. Put others at ease in your company so that when they need your services or want to refer someone to you, they will not hesitate.
5. ***Philanthropic events:*** Philanthropic events are an important way for a physician to give back to the community and to create goodwill. You may find the audience is not of the demographic you would ordinarily attract, but giving

of your skill and time is recognized and appreciated. Make the most of it, using these occasions for media relations, announcements, and demonstrating for your existing patients and referral sources that you selflessly give to others.

6. **Viral marketing:** Viral marketing is “the buzz.” It’s what you do to get everyone talking, sharing, forwarding, listening, and engaged in your message for reasons that sometimes have little to do with you. Although it may originate as advertising, viral marketing is a ploy designed to be so intriguing, so infectious that people share it.
7. **Social networks:** Social networks range from Facebook, Twitter, and MySpace to LinkedIn and Yelp. There are general social networks for making friends, and specific social networks. The premise of these networks is that you establish yourself with a profile (information about you), and then you network with others on the site through blogs, chatrooms, email, and instant messaging. These virtual communities have rules, but that does not prevent people from acting dishonestly or maliciously. Social networks are for social discussion and connection; they are not a place to give advice or solicit patients. Even if you don’t engage in social networks, you should know what they are and monitor them, because your patients may just be talking about you.
8. **Sharing:** Sharing is a means to post videos, images, and stories on YouTube, Flickr, or a multitude of other sites. The reality is that although these sites are affordable (no cost) and accessible, they are not an effective means to reach out to a prospective patient or a wider audience. Such sites are generally unmonitored and somewhat unrestricted, and you may find that your well-intended message has morphed into something damaging to your image.
9. **Blogs:** A blog (the term is derived from Web + log) is an online “diary” on which people post commentary, share experiences, ask questions, and engage in conversations. Blogs are often read by those who don’t participate. Like social networks, blogs have rules, but sometimes it is unclear who is monitoring to make certain participants follow the rules. Some physicians choose to start their own blogs on their own website or intranet for patients to ask questions and discuss topics of interest. This may be beneficial to your audience, but if you start a blog, you need to keep it fresh and moving. Much like social media, although you might not want to spend the time on blogs, you should know what they are and monitor them carefully.
10. **Reviews:** Reviews of physicians, medical procedures, and beauty products are available online. You may be the subject of a review and not know it; multiple sites crop up that offer patients the opportunity to anonymously review your practice and your services. The best way to know where you are reviewed or discussed is to regularly search for your name and brand through a search engine and see what listings come up. Contact the webmaster of any site that has incorrect information about you. They will likely try to sell you enhanced profiles; however, they must either correct erroneous information at no charge or remove your information from their site.

11. **Wikis:** Wikis (the term is derived from the Hawaiian word for “hurry quick”) are sites with collections of Internet content that are interlinked and can be accessed by anyone to add content. Wikis are for public education purposes, not for posting about oneself.
12. **Directories:** Paid or unpaid, this is so large a category that although it was once simply known as “yellow pages,” now it is an outreach strategy all its own.

Directories

Directories come in print, electronic, and Internet-based formats; they can be very narrow (all the physicians on staff at your local hospital) or broad (the national directory of all members in your specialty society).

Measuring response with directories is essential to managing the expectations you have for your effort. Exposure is the first consideration; who will see you, and how will they find you? Then it is a question of what communication vehicle specifically prompted an individual to act and contact you. Electronic directories have the added advantage of built-in tracking mechanisms. However, such systems measure numbers, not the quality of connections. The most reliable method for measuring response to any communication strategy you employ is to simply ask those who engage your practice these questions and track the responses:

Who or what referred you to our practice?

Where were you exposed to a message about our practice?

Where did you obtain the information you used to contact us?

Media Relations

Media relations include interviews, press releases, and story placement (publicity); they provide opportunities for you and your practice to be a source for public information on the subject of your profession and practice. There are two ways to engage national and major market media relations to garner publicity:

1. If you are a strong enough presence and personality who has significantly greater value or standing than your professional peers, you can drive your own media relations efforts.
2. If you are a strong, dedicated, and articulate personality who is active in research or teaching in your specialty; in the local, regional, national and international professional organizations you belong to; and with companies who manufacture or supply the treatments you administer or sell, you will have value to a media outlet. You can garner media relations through your contribution to these groups, either by driving your own media relations efforts, by partnering, or by acting as a spokesperson for the group you represent.

You must accept how media relations efforts are driven and realize that if you want reputable media coverage through channels that have value to your target popula-

tions, you must adhere to the principles of ethical media relations, and to your own principles.

Once you understand the principles of media relations, determine how you wish to communicate with media, whether you want to direct your own efforts or engage others, and the results you expect. Know who to contact to regularly update your contacts. For your message to be effective, it must be placed directly in the hands of the journalist who can most effectively use it to fulfill the interests of viewers, listeners, or readers.

Essentials of Media Relations

Whether you engage the media or you are approached by a media outlet, there are some media training basics to adhere to, regardless of how well you know or trust a journalist:

- Make certain the journalist or media outlet has integrity and that your message will be fairly and accurately transmitted.

- Prepare carefully for any meeting or interview. Ask for the specific focus and your expected contribution to any comment or interview as well as an agenda so you may prepare accordingly. Practice the dialog you expect to provide with any journalist. When this conversation does take place, have any supporting information you may wish to provide at hand for easy referral.

- Ask to review any portion of your contribution to a media effort for clinical accuracy. This is fact-checking to ensure that you are not misquoted; it is not editorial control. Do not make the mistake of telling a journalist how to present his or her story, or you will never again be a source for media relations.

- Protect patient privacy when media are present on your premises or when speaking with media. Certainly the best story is a personal story; involve your patients in a general way when possible and be candid about the effort. If a patient agrees to participate in your media relations efforts, you must obtain a release from the patient for his or her participation, whether this is to be in person or through photographs, even if the patient is not readily identifiable in the photographs. This cannot be a quid pro quo arrangement (in exchange for free service) unless that service is nominal and unattached to the effort at hand.

- Communicate effectively and consistently with any media organization. Provide supporting data, follow up all questions with supplemental information, and be sure that you know when your contributions will be broadcast or printed so your office staff will be ready to field any phone calls or inquiries that result.

- Maintain the media relationships you develop with verbal and written expressions of appreciation, similar to what you do to maintain your relationships with patients through correspondence related to patient care and innovation.

Advertising/Editorial Hybrids

Paid advertising today is often not limited to an ad; in many cases short articles, profiles, and even full-length feature stories can be bought in publications or on radio or television. You may even participate in a special advertising section on a specific theme in a local publication. Meant to look like unbiased editorial content, these hybrid pay-for-play efforts are commonly referred to as *advertorials* (advertisement + editorial). These hybrids contain artwork and editorial content and are disseminated or published for a fee. An advertorial can be placed in a defined section within a publication that is labeled as advertising, or it can be supplied content included in a local publication. All hybrids, whether simple advertorials or paid programming, must be contracted as advertising, and you must carefully review the fine print.

Advertorial: Most ethical and credible publications will state clearly that advertorials formatted to look like articles are advertisements. A quality publication will distinguish any paid messages from editorial content that is researched, attributed, and vetted as factually correct and balanced. Such a publication does not want to lose its reputation for objectivity or confuse or mislead its readers. They do not want to appear to recommend, feature, or present a product or service that has not been researched and reviewed through appropriate channels. If you are not willing to have the advertisement labeled as such, then your intention is to deceive. If the publication allows an advertorial without labeling it as advertising, its policies and format should be clear to readers so they can easily distinguish between paid and unpaid content.

Special advertising section: Regional and metropolitan publications often include special advertising sections on a specific theme that allow a templated advertisement (a photograph and a set number of words), or a mix of advertising and content at special rates. If you know the context of the special section and all the other businesses, products, or providers featured, and are comfortable being showcased among this group, a special advertising section can be a positive method for reaching a focused audience. If the section is unlimited in how many providers like you are included, or undefined in the selection process of those features in the special advertising, it is best not to be lost in a sea of unqualified providers or diverse and unrelated products and services.

Paid programming: There have been many instances of television or radio programs that appeared and disappeared for which a physician was offered the opportunity to be featured in a documentary, or to star in his or her own program if he or she raised sponsorship dollars or paid a fee. The results of these programs are questionable. What you spend on paid programming is better invested both in time and money on efforts to connect with serious prospective patients rather than those who randomly connect with your radio spot or television debut.

Pay-to-play: In pay-to-play, a medium offers to mention you in an editorial context in exchange for your advertising. Although publications and programs should support their advertisers, they should never be so brazen as to offer

pay-for-play, nor should you demand such a deceptive practice. If you have an established relationship with the medium, use it as a resource, and their representatives will reach out to you with questions about your practice or upcoming story ideas. If you cannot truly claim to be an expert on a topic, paying to be recognized as one will not yield positive results.

Paid features: An interesting phenomenon has emerged that combines several articles or program segments featuring various topics or physicians to create a full publication or program. These paid features are just that: the opportunity to pay and have a well-trained editorial team shape an article or a segment about you or feature you as the expert on a topic of interest, such as anti-aging treatments. Look carefully at the publication, the program, and all the other topics and providers featured. In most cases, no matter how straightforward the professional intent, these are easily identified by your audience as paid efforts.

ONLINE MARKETING TOOLS

ANDREW R. BERGER

Today one of the most important means of promoting your practice is through online marketing tools. Your website creates a picture of you, your credentials, your practice, and the menu of services you offer. Various communication tools can help spread the word about what's new with your practice, upcoming events, cutting-edge procedures, and results. Newsletters, social networking, and blogs, among others, are all part of the new media that are helping to define the current online communications that doctors and their practices need to understand and implement if they want to grow their practices.

Your Website

A well-designed website that has been optimized for Internet search engines is also an important and effective marketing tool, and if planned effectively, does not have to be a drain on the practice's resources. Rather, it can provide a positive source of new patients and revenue and serve as an educational tool for your patients.

Design

Your visitors' first online impression of your practice depends on your website's design; therefore it should be both aesthetic and professional in appearance and easy to navigate. Many visitors judge the quality of content within the website by the organization and design of the overall site. Your company's logo and colors should be used throughout the site, creating a consistent look and feel. Slight variations in de-

sign between different sections can enhance your website if used appropriately, but drastic shifts in appearance can leave your visitors disoriented. It is essential that your website's design be unique to distinguish your practice from the myriad sites offering similar services.

Content

Your website's design invites visitors into your site; the content of your website should hold their attention. Content is the core of your website. Even the most aesthetically pleasing site will attract few users if it is not informative. Well-thought-out content not only educates your visitors about your practice but also encourages repeat visits. Furthermore, having relevant content plays a pivotal role in search engine placement and greatly increases link popularity to your site.

Search Engine Optimization and Submission

Every day search engines (programs that search for and list Internet documents containing keywords or keyword phrases) direct millions of Internet users to their online destinations. It is likely that your website will receive more than half of its visitors from these search engines. Therefore your website should be developed in such a way that major search engines and indexes can easily catalog and search your content. Depending on the search engine, it can take anywhere from hours to months for your site to be listed. Once optimized and cataloged properly, your site will gain visitors who type in keywords relevant to your practice.

The various search engines frequently change their algorithms to ensure that they get a variety of relevant results. There are a number of techniques you can use to achieve more prominent search engine placement. None of these techniques will guarantee you the top spot in all of the search engines; however, following these principles will significantly improve your website's search engine placement.

Selecting relevant keyword phrases (not just keywords) proves exceedingly important. For instance, in addition to selecting "plastic surgery" as your keywords, choose "plastic surgery in Boston" or "Botox in Boston" as well. Be as specific as possible.

These keyword phrases should persist throughout the following elements of your website: website title, uniform resource locator (URL; your website's "address"), meta tags, and content. Although sprinkling relevant keyword phrases throughout your web design will improve your search engine placement, flooding your web pages with keywords may have a negative impact. Many search engines may ban you for overusing keywords, and your visitors will show little interest in content that is so compromised by keyword phrases.

An abundance of relevant text content is as valuable to search engines as it is to your readers. Search engines catalog all the text information from each of your web pages. The more text content information you have cataloged in the search engines, the greater the chance search engine users will find your website in their query results.

Link Exchange

Link exchange is one of the most effective ways of attracting targeted visitors to your website. Aside from search engines, most users find new web pages through other related websites. In a link exchange, the owners of two websites agree to place each other's links on their sites, usually for free. Understanding how to make the most of link exchanges is crucial to increasing your site's traffic.

Link exchange has a direct effect on your site's link popularity, which is the number of links that point to your website as measured by the search engines. Since the objective of search engines is to serve those sites that are recommended by many other sites, most incorporate popularity factors into their ranking algorithm. The quality of the sites linking to you, however, is being closely examined as well. Therefore it is important to get links from popular websites whose content closely relates to yours. Getting only a few links from popular websites will be more useful than getting several links from less-popular websites.

The easiest way to look for link partners is through the search engines. Enter your keywords to find out which sites get listed first, and then contact each site owner to suggest a link exchange. If most sites listed are your direct competitors, come up with related keywords instead. For instance, if your area of specialty is rhinoplasty, look for sites that deal with other types of facial plastic surgery. You may also be able to exchange links with related publications or professional associations. If you have an online newsletter, submit its link to online directories that are reserved exclusively for newsletters.

Visit a site before asking its owner for a link exchange. Try to personalize your link request email instead of sending an automated message to every site. In your email, always suggest a title and short description of your site that may be displayed on the link partner's website. Your main keywords should appear somewhere within the title, the description, or both.

Aside from link exchanges, offering quality content on your website is an indirect way to increase your link popularity. People generally link to websites that offer unique and useful information and will do so without being asked. Another way to promote your site is to allow other websites to display your site's content in exchange for a link back to you. In summary, the more links your site has from quality websites, the more traffic your site will likely receive.

Online Advertising

Aside from search engine submissions, you can market your site through pay-per-click or pay-per-impression programs. A pay-per-click program typically places a text link or a banner ad to your website and charges you a flat fee each time a visitor clicks that link to visit your site. Although a pay-per-impression program also places a text link or a banner ad to your website, it charges a fee based on the number of visits (impressions) to the web page your link resides on. When considering these programs, select only programs that place ads on sites that attract visitors within your target market. Generally, pay-per-click programs and text links have been shown to be more cost effective than pay-per-impression and banner ads, respectively.

How Many People Visit My Website?

To effectively run an online marketing campaign, it is important to determine not only your initial level of website traffic (the number of visitors to your website), but also any changes to these traffic levels in response to your marketing activities. This will help you assess the effectiveness of your marketing campaigns as well as the activities of outside consultants or services you might hire to assist you. The web server, which is a computer where your website resides, likely already has installed website statistics software for tracking website traffic. You can communicate with your website hosting company to determine whether you currently have one of these programs available to you. If not, they can usually be added to the web server for about \$100 to \$300 a year.

eNewsletters

Newsletters are effective marketing tools that serve a dual function: educating your patients and promoting your practice. With the growing popularity of medical newsletters and the enormous interest in aesthetic surgery, it is only natural that a well-constructed newsletter will provide an effective vehicle for communicating your message to current and prospective patients. Although traditional newsletters can still be effective marketing tools, eNewsletters provide some distinct advantages over their print counterparts, both in efficiency and economy.

eNewsletters are a relatively inexpensive way to communicate with patients. Professional email marketing services can cost as little as \$25 to \$50 per month for an email list of approximately 2500 emails and allow unlimited email marketing campaigns to your list. By comparison, one traditional newsletter with print, design, and

postage costs could amount to more than a year's worth of email marketing service. Keep in mind that most of these services require that your email lists are "opt-in," which means the emails within the list have been voluntarily given to you by your current or prospective patients and have not been purchased. Although initially this requires some additional effort to acquire and build your email list, your growing list will lead to increasingly effective direct marketing campaigns.

Today creating an online campaign through an eNewsletter service is an easy process and does not require technical training. These services provide you with simple templates and a wide variety of design formats. All you need to do is fill in your message. Keep your message focused, and provide embedded links throughout the email to various pages within your website, such as announcements of new services, honors received, new developments in plastic surgery, and office contact information. Distribution is instantaneous through a click of the mouse and can be scheduled for launch at any time.

A variety of features within these services will greatly aid in growing your eNewsletter community while allowing you to efficiently run your campaign and track its effectiveness. Simple link features such as "Forward to a Friend," "Update Profile/Email Address," and "Unsubscribe" will help you easily manage your eNewsletter subscriptions. Consider selecting a provider that offers statistical information on the number of subscribers opening the newsletter and visiting your website through embedded links in your email campaign. These statistics can help you fine-tune your newsletter based on your subscribers' actions.

You can promote your eNewsletter by featuring it in brochures and other printed materials and on your website. Choose a service provider that supplies a referral button within each newsletter for readers to forward the information to friends and relatives and a sign-up button for these new contacts to join your subscription group. Newsletters provide an inexpensive means for maintaining regular contact and building relationships with your current patients, as well as capturing and educating prospective patients.

Getting Help

Admittedly, most surgeons don't have time to personally develop their online marketing program and will hire a company to handle the details. The descriptions presented here outline factors that are important in a successful online marketing ef-

fort. The following are some important considerations for your online marketing campaign:

Purchase your own domain name: Make certain you purchase your own domain name and that it is on an automatic renewal system for annual registration fees. Domain names can be purchased for about \$10 per year from a domain registration company.

Use a website statistics package: To assess the effectiveness of your online marketing campaigns, it is essential to determine not only your initial level of website traffic, but also any changes that result from your marketing activities.

Create a pleasing website design with relevant content: Develop a website that is aesthetically pleasing to your visitors while educating them on the procedures and services you provide. Websites full of relevant content are more easily “seen” by the search engines and are more likely to result in return visitors.

Use eNewsletters as cost-effective marketing tools: These campaigns can help you to promote your practice economically and efficiently while assessing the potential interests of prospective patients by tracking clicks on embedded links in your email campaigns.

Establish link exchanges: Building large link exchange networks with related websites can greatly assist in search engine placement. Remember that the quality of the incoming link is usually more important than the quantity.

Enhance your potential for search engine optimization/submission: Keyword phrases should persist throughout your website design: website title, uniform resource locator (URL; your website’s “address”), meta tags, and content. Although sprinkling relevant keyword phrases throughout your web design will improve your search engine placement, flooding your web pages with keywords may have a negative impact.

Concluding Thoughts

FOAD NAHAI

It is extremely challenging to develop and maintain a successful aesthetic surgery practice, and not without significant financial risk. It requires hard work, planning, and perseverance. Before setting any goals, the surgeon must assess his or her strengths and weaknesses. We all have areas of interest, procedures that we excel in and others that we don’t do as well. The practice should be built around the strengths of the surgeon or surgeons, taking into account competing practices. For example, if there are several surgeons in your community who excel in breast augmentation but there are none who perform rhinoplasty, provided you have the skills and interest, your practice should focus on rhinoplasty where you have an opportunity to gain significant market share with little competition. A successful cosmetic medicine/aesthetic surgery practice is built around patients and their needs. Surround yourself with qualified, motivated staff members who share your vision and commitment to patient safety and customer service.

Clinical Caveats

The practice model directly affects the surgeon's working environment, control of everyday decisions, financial independence, and flexibility of schedule.

The total patient experience, including his or her encounters with all aspects of the practice, is just as important as the quality of the result of a procedure.

To run a successful practice, a surgeon must have a basic understanding of the business aspects of daily operations and a budget and plan for reaching the goals that will drive the practice.

Regularly scheduled staff meetings nurture a sense of teamwork and emphasize the important role everyone plays in the success of the practice.

One of the best ways to attract patients is to become involved and to make yourself available as a speaker and educator, as a source of information for possible referring surgeons, as an advisor to support groups, and as a local authority.

The patient coordinator serves as a vital link between the surgeon and the patient, and must be able to connect with patients on a personal level and to instill in them trust and confidence in the surgeon and the practice.

Computer imaging helps to establish better communication with patients to define goals, develop an appropriate treatment plan, and effectively communicate expectations by demonstrating what is and is not possible to achieve through surgery and adjunctive treatments.

A well-designed and optimized website is an essential tool in today's aesthetic surgery practice.

Annotated Bibliography

Baum N. *Marketing Your Clinical Practice: Ethically, Effectively, Economically*. Sudbury, Mass: Jones & Bartlett, 2000.

This easy-to-read practice management book provides helpful information on marketing approaches to promote practice enhancement.

Beckham DJ. *Marketing Your Practice—A Practical Guide for Physicians*. Arlington Heights, IL: ASPS Health Market, 1986.

This plastic surgery guide provides useful practice management advice in a loose-leaf format.

Brown S, Nelson AM, Branch S, Wood S. *Patient Satisfaction Pays*. Gaithersburg, MD: Aspen Publications.

This is a must-read book for anyone considering practice enhancement. It provides important information on strategies and practical approaches for dealing with patients.

Kuechel M. *Aesthetic Medicine: Growing Your Practice*. St Louis: Quality Medical Publishing, 2009.

This book provides an overview of the issues to consider in running an aesthetic surgery practice with numerous practical suggestions throughout.

Nelson AM, Wood S, Brown S, Branch S. *Improving Patient Satisfaction*. Gaithersburg, MD: Aspen Publications.

This publication provides helpful information on patient relations.

Starr P. *The Social Transformation of American Medicine*. New York: Basic Books, 1984.

This book provides an evolutionary account of American medicine since its inception. It supplies an excellent background of the social factors that have influenced and continue to influence American medicine and insight into how American medicine has metamorphosed into a megamarketing industry today.

CHAPTER 7

The Practice: *Staffing, Services, and Financial Planning*

MARIE CZENKO KUECHEL

There was a time when an aesthetic practice was all about outcomes—the physical improvement that resulted from aesthetic surgery. Today, managing your aesthetic surgery practice involves a combination of inextricably linked factors, including producing good outcomes, interacting with patients, empowering staff members who excel, providing services that meet patient needs and are priced affordably yet profitably, marketing to promote treatments, and communicating to educate your patients.

This combination is essential for achieving patient goals and managing a lucrative aesthetic surgery practice in a competitive environment in which other providers and multiple options vie for consumer dollars. Whether to invest in surgery or a luxury vacation, a car, or even a piece of jewelry is a decision your prospective patient must make; the answer depends on the physical desire and outcome, but also on the experience. Although your outcomes and interactions with patients may be your responsibility and under your control, your staffing, services, financial considerations, and marketing rely heavily on the efforts of others and on variables that may be out of your control.

Managing your aesthetic surgery practice begins with staffing and services and includes your financial model and marketing strategies (which are discussed in depth in Chapter 6). One might call these the core factors for aesthetic surgery practice management.

Staffing

The staff members you employ will interact with your aesthetic patients. In most cases these individuals are the first and last point of patient contact, perhaps even the primary contact. They are your messengers, gatekeepers, spokespersons, and advocates. Before you consider whom to recruit and what qualities your team should have, consider the diverse skills that staff must possess to work collaboratively. Ideally, your staff should include four functions—service, clinical support, patient management, and administration—that are integral to managing your practice and achieving patient expectations. Whether employees or contractors, staff are part of your team and essential to your daily operation.

Service Providers

Today's aesthetic practice commonly requires more than a surgeon providing services intended to achieve specific aesthetic outcomes. *Physician extenders* (physician assistants or registered nurses) and, in many practices, aestheticians provide services to complement aesthetic surgery or to achieve specific aesthetic goals that may not require surgery. Fundamental to managing these individuals is the understanding that this is your practice, these patients belong to your practice, and these providers are an extension of you. They may be permitted or required to act autonomously based on their individual expertise and on patient needs, but how, when, and to what extent can only be defined by you, within the parameters defined by state law and your profession.

Clinical Support

Whether exclusively supporting you in the operating room or fulfilling a dual role of providing aesthetic services to your patients and clinical support to you and other team members, clinical support staff are essential; no one can function alone. The individuals who provide clinical support are essential for managing patient expectations; they may be the ones who allay patient anxieties before surgery, administer anesthesia, or provide assurance and comfort immediately after surgery. Or they may be invisible to your patient, such as the scrub nurse who rarely ventures outside the operating suite or interacts with conscious patients. Those who come in contact with your patients must accept the demands of managing expectations at all times. Because of this intricate interrelationship among support and provider roles, it is vital that the scope of service and clinical support functions be clearly defined in job descriptions, be well communicated among the team members, and be appropriately scheduled.

Patient Management

The term *patient coordinator* has been coined to describe the role of the individual responsible for patient management. In some practices this function is performed by a nurse or another clinical support person. Titles are less important than are the dedication and skills of the individual who fulfills the patient management function. This professional is a vital contributor to your team and is responsible for managing the entire patient experience, including all the documentation and related communications. The patient coordinator is the pulse-point for your patient. This is not a position to entrust to a commissioned, contract, or consulting individual; patient management must be a vested function in your practice. For an aesthetic surgeon who is strong on clinical skills but short on interpersonal skills, the patient coordinator is not merely a vital contributor; he or she is the most important member of your team, because without this person, you may not have patients who will accept your services. (See Chapter 6 for a detailed discussion of the patient coordinator's role.)

Administration

Office manager and *receptionist* are common administrative roles in the practice. Most often these are full-time employees, but these functions can also be supplied by office management consulting firms that assume responsibility for the business aspects of your practice. Effective data management is essential to successful administration; this will take the least amount of effort if it is conducted in a timely, systematic, and well-organized fashion. Administrative roles may be very focused, or broad based to include financial and operations management, property and facility management, and human resources management. I don't believe in hiring someone whose only function is to serve as a receptionist; every person in the office must be capable of and responsible for answering the phone and greeting visitors.

Your team may be lean, efficient, and diverse in their duties, or may include multiple individuals and layers for providing service and administrative support. There is no one model that characterizes all aesthetic surgery practices or a single operational skill set held by all surgeons or business owners. It is important to recognize that the number of providers, the pace of your practice (number of procedures performed), and the mix that exists in your service model will all factor into determining the right number of people to employ. In addition, your surgical team, whether provided by the hospital or surgery center where you operate, or employees or contractors at your own office-based or ambulatory surgicenter, will also influence the ultimate number of team members you require. Your own surgical staff can multitask to perform preoperative and postoperative functions and even provide such services as injections, making your team more diverse in talent, although more limited in numbers. An outside surgical team can free your in-office clinical staff to provide appropriate nonsurgical services while you are in surgery, creating an added revenue stream, or may carry out essential patient management functions. There is no single model. What is more important than the number of people on your team is their contributions and loyalty to the practice and to your patients.

Every person on your team must be loyal to you and to the practice. All team members must thoroughly understand your specialty, as they should in any medical practice or business. In addition, they must be willing to continuously learn and keep current with the advances in your specialty, even if that includes services you do not provide. An aesthetic practice requires individuals who fully understand the uniqueness of providing elective services and are willing to meet the expectations of patients who have very specific physical and experiential needs. They must be discreet, warm, compassionate people who also know when and where to draw the line, because they will regularly become involved in the most intimate details of your patients' lives, bodies, and choices.

Recruiting

Throughout your practice career you will either need to hire more staff or to replace those who leave, from the natural process of turnover or because they are dismissed. In recruiting staff, two questions need to be addressed:

1. Where do I recruit quality staff?
2. Should I hire based on skills or personality?

Your staff, particularly those with direct contact with clients and patients, must be chosen based not only on skill, but also on personality and presence. An individual with the wrong personality or image for the position does not easily change, but with the right foundation, skills can be honed or acquired. Personality is the critical variable. Staff members represent your practice as much as you do. In fact, in almost every case, they are the first in-person impression a patient receives of your practice. They do not need to be a physical model of aesthetic perfection or a mirror of your finest work. They do need to be articulate, kind, patient individuals who understand that appearance is an important personal issue for the patient.

Where to Recruit?

When the need arises to fill a position, the best place to start is always from within—to nurture current team members with the potential to fill the role, or to engage them in helping you recruit other talented individuals with whom they will have to work as part of your team. When you don't find the right candidates among this internal network, you should look outward, but slowly. Look to similar (not necessarily the same) businesses or practices for the right basic skills and the essential personality traits. You can train and educate a capable individual, but you cannot overcome personal or service deficiencies that will be obstacles to your patients' having a consistently excellent experience.

Screening

Recruitment only begins with finding appropriate candidates for the job. Critical to recruitment is screening. Interviews should be conducted not once, not twice, but at least three times and should include the following components:

- Email correspondence beyond the presentation of resume and credentials
- Telephone conversation for a set period at a set time
- Face-to-face meetings with other team members and with the physician on one or more occasions

Before or during the interviewing process, you must check the candidate's references, understand his or her salary expectations, and explain the need for drug testing, a credit report, or other screening requirements before the individual may be hired. As you get closer to identifying the right candidate for a position, two things are essential: a demonstration of skills, and shadowing. Invite the candidate to spend a few hours or a day within the practice to get a feel for the pace, position, responsibilities, and office environment.

Once you have found the right candidate and have screened appropriately, you can make the decision to add this individual to your team. But remember, this is a team—so include other staff members in the decision-making process, because they will be working together in managing and meeting expectations in your practice.

Qualities to Hire in Your Aesthetic Practice

Competencies and personality are obvious factors in determining whom you will hire. From the front office staff to the scrub nurse, those on your team should also possess the following qualities.

PRIDE Taking pride in oneself, in one's appearance and actions, in one's work, in the team, in your business, and the services it provides is essential in a service-oriented business that is inextricably tied to appearance and self-esteem. Pride indicates a sense of self-worth; this is very different from being arrogant with a sense of superiority. It is important to recognize the difference and hire those who understand and strive for excellence in all aspects of their professional and personal endeavors.

RESPECT Respect is not simply reflected as deference given to the surgeon: every team member must possess an appreciation of patients, vendors, housekeepers, other staff members, and certainly the surgeon. Respect must also be paid to procedures, systems, protocols, and patient privacy. Although you may not perform life-saving procedures in your practice, they are life-changing for many, and they also carry the potential for risk; staff must understand and respect these potential risks and the impact these procedures have on patients.

A THIRST FOR KNOWLEDGE Those you hire must want to both learn and teach on a regular basis. Exceeding expectations in the aesthetic surgery practice requires a strong and empowering connection between your staff and patients to educate them beforehand about the possibilities, responsibilities, and limitations involved with surgical procedures. In that process questions can arise. An educated staff with a thirst for knowledge will always seek the answers they don't have, confirm the validity of those answers, and convey these facts. You will also need to continually upgrade your own skills, keeping pace with technology, techniques, and best practices, and differentiating between valuable learning and overhyped training.

HUMOR The ability to laugh is essential in the work environment. It is also, in good taste, a means to allay anxiety, to establish a connection, and to deal with stress. Staff with a sense of humor and good taste have the ability to keep the team or a patient at ease and engaged.

PATIENCE A service business as intimate as aesthetic surgery requires people who exhibit patience for the client, the process, and all associated emotions, details, and potential complications. Efficiency is important, but not when it forces others to be hurried, or to overlook details, or when impatience becomes obvious and affects team cohesion. We all have moments when a patient or situation has taxed our tolerance; it is important to respond by regrouping, or revisiting the situation at a time when everyone has a fresh perspective and the ability to focus again on the importance of the situation. Decisions or actions made impatiently are not confident decisions or actions.

Training

Specific training was once thought to be an essential prerequisite to working in an aesthetic practice. Today, however, we recognize that training is an ongoing process in a service-oriented business. Although the foundation of the practice may remain constant, the service mix may change to adapt to the introduction of new treatments, technologies, and techniques. As much as your credibility is the core of a successful practice, so also is the credibility of those who work with you. Clinical staff have a duty not only to keep abreast of new information, but also to remain current on skills and training. Encourage this, reward this, display the certificates, and communicate your staff's level of knowledge and training to your patients. Recognition of individuals' growth in the performance of roles contributes substantially to their job satisfaction and ultimately to employee retention. Administrative staff have a duty to keep abreast of market, operational, and business knowledge. This should be rewarded, and the value of advancement should be communicated to the entire staff, because it will inevitably benefit everyone in the practice when administrators can improve the skills that make the practice succeed.

Training Essentials

The aesthetic world is changing rapidly. It is essential that new skills, technologies, and treatment protocols that add value to your service mix be thoroughly investigated and honed before adding them to the service menu. Without training, whether from a book, a seminar, a webinar, or other professional resource, you and your staff cannot progress.

Respond to trends. Learning about the trends and procedures you will not offer is as essential as mastering new skills. Today's patients are well educated and have access to an overwhelming amount of information, both credible and of dubious value. To respond intelligently to questions about the treatments and services you do not offer, you need to first understand what those procedures are and be able to state succinctly why you have decided that these do not have value for your practice and your patients.

The aesthetic practice faces daily service and clinical challenges, but what is often lacking is a long-range goal that challenges the individual to progress and grow. It is important to seek new learning opportunities and to promote training that allows you and your team to be stimulated by new, positive, and potentially lucrative opportunities.

Managing

Nurturing and growing your staff as well as managing them is critical to maintaining a strong team. The human resources function is essential, no matter how small your practice or how successfully and harmoniously your team members work together. Management basics include the responsibilities of hiring, payroll, benefits, and policy. You may personally manage your team, or you may choose to empower someone on staff to manage and make final decisions. You may choose to outsource the payroll, benefits, and other human resources functions; you should outsource drug testing or competency tests. Internally, there must be a decision-maker and manager you can rely on to manage compensation, which includes all things provided to your staff in exchange for services: salary, bonuses, or commissions, insurance, and even perks such as treatments. Forms of compensation should not be chosen lightly; they should be researched and defined in your practice policy. The process of reviewing staff contributions, goals, and growth is the most often overlooked basic component of a staff cycle in any small business, and it is inextricably tied to compensation.

You must review performance annually as well as oversee the day-to-day methods and competence with which your staff addresses your patients' needs. We have all seen the difficult patient, the one with unreasonable expectations. We have also seen what happens when a staff member, innocently or during a moment of pressure, contributes to a service failure or implies an unrealistic or unattainable outcome. It is the manager who must resolve these problems for the patient and the team. Can the team member be retrained, or must he or she be terminated?

There will be times when an employee must be terminated, whether for performance issues, in response to economic pressures, or for other reasons. Whether it is you or your manager who carries out the termination, this is stressful. Terminating any individual requires adherence to guidelines defined by law. Acting within the confines of your practice, you must progress with your remaining team, answer the inquiries of patients, and carry out all the functions necessary to continue to serve your patients.

Essentials of Staff Management

ENCOURAGE RELATIONSHIPS Staff members should be encouraged to forge appropriate relationships with their coworkers, the aesthetic surgeon, vendors, and your patients. Clearly state your expectations for the relationships within your practice, and define your expectations for relationships outside your practice, whether family, friends, or acquaintances of your staff. For example, value the patients who come to you for services as a result of a personal or professional relationship with your staff members, and define how you might—or whether you will—offer special pricing, services, or perks to those individuals.

DEFINE BOUNDARIES Some actions are simply not acceptable, such as when an employee contacts patients outside the office. An individual's one-to-one contact for reasons other than the professional needs of your practice is unacceptable. Other boundaries include behaviors such as dress, manners, language use, and even the use of office equipment or conducting personal business on office time. An employment manual that defines everything from dress code to personal calls, Internet usage, and personal use of office supplies is essential to defining and maintaining boundaries.

KEEP AN OPEN DOOR It is essential that you maintain open communication with your team about minor daily events or major concerns and about practice or personal issues that may affect an individual's performance in your practice. Don't dismiss a matter out of hand that seems trivial; listen, put it in perspective, and move the conversation to important matters. Although you should not get involved in personal staff issues, knowing that a member of your team is going through a divorce, the illness of a parent or child, or other problems that may hinder his or her ability to work is essential to your leadership. An open door will help you remain apprised of matters that affect the morale and pace of your office and will establish a level of trust between you and your team.

MAINTAIN RECORDS Human resource records include employment applications, verification of eligibility to work in the country of residence, bonding, drug testing, salary, raises, bonuses, benefits, and performance reviews, performance infractions

and warnings, emergency contact information, certificates and licensure, added skills (such as fluency in a second language), and essential health records (for example, TB test results). These records are all essential to the business health of your practice. You may not wish to be the keeper of these vital records; appoint a trusted and appropriately trained leader to manage this function on behalf of the practice.

LEAD BY EXAMPLE If you expect a staff of timely, top-notch, talented individuals, you too must present that standard. A surgeon who consistently walks in the office moments after the first patient for the day has arrived but first addresses emails, messages, and other business sends the message that patients can wait. We all have bad days, but you must consistently set a tone of mutual respect that demonstrates what is acceptable behavior and what is not, and a tempo that is efficient and professional.

Team-Building

Recruiting and hiring staff requires immense effort; a weakness or void in a staff position is taxing for everyone. Loyalty among your staff, motivation for your team, and rewards that recognize staff accomplishments are critical to staff contributions and retention and help to maintain consistency and continuity in your practice.

Employees' loyalty must be to the team, the patients, and the surgeon. The different providers, functions, and personalities involved in managing your patients' needs and expectations are not mutually exclusive; success happens as a result of the team's efforts. Recognize that you are the team leader; your actions, decisions, interactions, and transgressions will have an exponentially higher effect on the team than those of any other individual. Set the bar high, and recognize that loyalty must be earned daily; it is not intrinsic to your role as the surgeon.

Rewards are essential to motivation; various motivating factors spur different individuals. For some it is money; for others it is praise. Some are motivated by advancement; others are inspired by the fulfillment and satisfaction they receive from accomplishing daily tasks and specific goals; and others are gratified by their role in helping patients to achieve their desired outcomes. Motivate in a manner that is valued by the individual and beneficial to the team. Motivate team members daily when things work well, or when conflict is managed. Encouraging words and leadership are essential in difficult times; without them morale and subsequent enthusiasm and desire to meet challenging expectations will wane.

Five Essential Teams in Your Practice

You may have a staff of three or 30; regardless, the following teams are essential to collaborate on a number of functions within your practice.

Clinical: Whether in the office or the operating room, those who provide service or maintain records of service to patients must work together and meet as a team to review everything from individual cases to processes, and even preferences in supplies and scheduling. This team will also review and critically evaluate data on new procedures, techniques, drugs, devices, protocols to determine what can and should be added to the service offering, and what falls outside your scope of practice or standards for excellence.

Operational: The people who keep patient traffic moving into and through the office are a team that includes both providers and administrative staff. Everything from waiting times for appointments, waiting times at appointments, patient data, payment, and even difficult patient situations must be on the radar of this team, whose principal goals are efficiency, attention to detail, and service.

Administrative: Those who handle calls, questions, accounts receivable, and accounts payable need to work in synergy and set the pace of the office. Information that is not communicated, payments that are not made or received in a timely fashion, and data backups and records that are not up-to-the-minute and secure all pose a serious threat of failure within your office. This team must consistently stay on top of details.

Patient services/marketing: Your service menu, amenities, pricing, patient expectations, website, consultation materials, community efforts, and all the things that are essential to attracting and servicing your patients fall under the purview of this team, who regularly check to see that correct, consistent, and timely messages, services, prices, policies, and other pertinent information are operational. Don't discount this team if you are a referral-based practice; their job is to also find and implement the most effective means for maintaining contact with your existing patient base and referral sources.

Quality improvement: A team of individuals who combine all of the key areas and monitor safety, accreditations, and other vital compliance issues serve as the critical eyes and ears of your practice. Their role is not nitpicking; it is quality improvement and the motivation for all to continuously do their best.

Services

The outcomes you achieve from the services you offer are the basis for your relationship with patients. A service model in your practice consists of more than the surgical procedures you provide; today it must include a multitude of nonsurgical treatments that complement or are preparatory to surgery, refine surgical outcomes, or stand alone as important services to fulfill your patients' appearance-related goals. Your service model is defined further by the menu, setting, and time in which you or staff members provide these treatments. It includes the amenities you offer your patients or the convenience and access to these services. It also includes the manner in which you address what you don't offer.

Service Models for an Aesthetic Surgery Practice

Cosmetic: Medical services that are elected to improve, enhance, or change personal appearance. You are dedicated to medical solutions that address the physical and emotional needs of your patients.

- *Surgical:* A portion of your services is dedicated to surgical solutions in your accredited on-site facility, an ambulatory center, or a hospital.
- *Nonsurgical:* Patients are treated medically, not with scalpels or by making incisions.

Retail: Products that are required or that enhance or extend your services are sold to your patients.

Spa: Services are provided in a luxurious and pampering environment. However, you don't need to call your practice a spa to surround your patients with warmth, comfort, and a relaxing environment.

The box lists the general models that shape a large portion of your practice, although these options will not wholly define your practice. The interest in and demand for innovations in nonsurgical procedures and treatments are burgeoning, but you will not limit your model to one category; you are a surgeon. Purely surgical practices are rare today; these are generally highly specialized and limited in the range of surgical procedures performed. The addition of nonsurgical services to a practice often begins with injections or skin care and may evolve to include energy, laser, and light-based technologies. Nonsurgical procedures are outnumbering surgical procedures nearly 4.5:1, according to the 2008 annual statistics of the American Society for Aesthetic Plastic Surgery (ASAPS). The increase in the popularity of and demand for nonsurgical procedures and the nature of their delivery has created a need and demand for physician extenders: licensed physician assistants, nurse practitioners, or registered nurses and aestheticians who administer treatment prescribed by the physician. However, according to a 2008 survey by the Physicians Coalition for Injectable Safety, 69% of aesthetic surgeons (board-certified plastic, facial plastic, or oculo-plastic surgeons) perform injections themselves in their practices.

Essential Elements of Service

Managing expectations in a personal service-oriented business such as aesthetic surgery requires looking at service as more than simply the treatments you provide.

SERVICE MENU Service in an aesthetic surgery practice can be viewed in one of two ways: as a diverse menu of items including surgery, nonsurgical treatments, and retail products for sale; and as a focused grouping of interrelated services that stem from your primary expertise—surgery. This includes skin preparation and rejuvenation to accompany facial aesthetic surgery, or hair removal to refine a newly sculpted leg or abdomen. It involves treating scars that have resulted from skin disease or surgery. Your service menu may promote other services, such as a patient who has re-

ceived injections of fillers and who now desires the more extensive and permanent results of a face lift. It may extend to a hair removal patient who likes her leg appearance and decides that she also wants her saddlebags improved for a total sculpted look. The service menu must be up-to-date: procedures, products, pricing, and packages. It is important to review data regularly to identify trends and measure productivity and profitability.

SERVICE SETTING Your practice setting is anywhere you offer services or meet and engage your prospective and current patients—your office, a surgicenter, a medical spa, or a satellite location. If you have more than one site, the atmosphere, appointments, privacy, and amenities offered should be consistent at all locations. There should be a connection, where one setting is an extension of another and all locations work together in concert.

TIMES OF SERVICE There are two approaches to the times you provide service to your patients—the times you designate that you will be available, and those times you make yourself available to meet patient needs. In a truly service-oriented practice, patients who request or require evening or weekend appointments get them. Surgery schedules are not defined by the physician alone; they are scheduled according to availability and the patient's recovery needs. Because you cannot be there for all types of services at all times, you must provide for supervision as appropriate and for physician extenders to respond to patient needs.

SERVICE PROVIDERS If your practice is to manage expectations and create an experience that is consistent in service and outcomes, all team members must be service providers, and their titles and goals should reflect that focus. The patient experience is shaped not only by the results achieved through an aesthetic treatment, but also by the connections he or she makes with each service provider.

The Operational Trilogy

An aesthetic surgery practice must focus on three distinct service entities: medical services, personal services, and retail. Each aspect has a distinct function, individual goals in fulfilling patient needs, and a unique contribution to revenue. Although each can stand alone, it is the synergy among the three operational segments that has the greatest value.

Medical Services

The medical treatment a practice provides, who the providers are, and where treatment is provided define medical services. Your skill and care and that of your clinical staff and supporting administrative staff represent the character of your clinical operations. The office, surgical facility, and postoperative care provided represent

the comfort of your operations. In an aesthetic practice the focus of care rests on ability, plus the basics of character and comfort:

- How and where do you conduct consultations?
- Who is your patient support advocate?
- Where are diagnostic tests performed, and how?
- What is the consent protocol?
- What is the preoperative protocol?
- Where is the operating room? How does it function?
- Who provides anesthesia and preoperative, surgical, recovery, and postoperative care?

The process by which you provide services to each patient builds an expectation that you must meet or exceed for every occasion in which this patient is treated. Aesthetic surgery today is not a linear equation, one where the relationship begins when the patient comes to you for desired treatment and ends with a positive clinical outcome. The relationship is cyclical for two very distinct reasons:

Nonsurgical treatments, commonly referred to as *cosmetic medicine*, are therapies that must be repeated, intensified, or changed to produce or maintain results. These may serve as a springboard to surgery as an individual continues in the patient cycle. If you cannot fulfill or maintain the treatment cycle, you have broken the cycle and lost the patient.

Happy patients are your best source of success and growth. Keeping happy patients in an active cycle maintains your visibility with them and reminds them of the value of your services. This will bring them back to you for different or added services, or they will refer others to you.

Personal Services

The services you provide are highly personal in nature. Whatever the extent or range of your service menu, the principles employed by the personal service industries are essential to your patients' experience and overall satisfaction. Personal services are reflected in the way you deliver treatment: by using clinical means to arrive at a physical outcome without the experience feeling medical; by practicing medicine with a team of talented, dedicated individuals who provide medical service while applying the principles of personal service; and by delivering an experience that is wholly based on personal fulfillment for the patient.

Some aesthetic surgery practices not only apply personal service principles to medical practice, but they also enhance the medical practice by adding true nonmedical services. Many practices thrive without them, some offer personal services but don't emphasize them, and still others call special attention to the personal services provided. Some of these personal services may be seen as nonessential, such as cosmetics, massage therapy, concierge services, and a car that delivers your patients home after a procedure.

The Potential Impact of Personal Services on Your Practice

Personal services may have the following effects:

Generate revenues or add expenses: They may produce revenue or increase your cost of operations or your investment in inventory. They may occupy space and require utilities, insurance, marketing, or other essential expenses.

Enhance your mission: Cosmetics were introduced in medical practices to help patients disguise birthmarks, scars, and acne, or telltale posttreatment signs such as redness, or bruising. They have evolved with science and improved formulations to become an integral part of the aesthetic practice, not only for correction and camouflage and for completing the full aesthetic experience for your patient, but also for maintaining results, protecting the patient's rejuvenated, youthful appearance, and nurturing the skin.

Create opportunity: Whether to improve your patients' experience, your ability to serve them, or to invite a new audience to your service business, nonmedical services must create opportunities for you to grow without having a negative impact on your resources or image, or your patients' experience.

Nurture ongoing relationships: Whatever the service, whether it is brow waxing or biofeedback, personal services that by their nature will be repeated by a happy customer keep your core services continually visible to that client/patient, thus creating a greater opportunity for your single greatest source for clients: referrals.

Definitions of medical services, personal services, or retail within your aesthetic surgery practice are straightforward. They intersect in the manner in which you provide them and in the outcomes, safety, ethics, and privacy that characterizes their delivery. Although treatment may create temporary pain, stress, and even fear, a successful aesthetic practice will create a positive, encouraging environment that does not discount these real conditions. Meeting or exceeding patient expectations requires the personal services of providing comfort, individual attention, and positive support.

Concierge Services

A concierge is often defined as a professional who assists guests in a hotel or members of a specific community, such as a condominium complex or a country club. In an aesthetic surgery practice, the term *concierge* encompasses the evolving concept of concierge services. It implies the ultimate in personal service to assist your patients in every aspect of the aesthetic experience. In reality, concierge services simply reflect common sense and common courtesy.

Components of Concierge Service

Attention: Your patients and their needs should always be the central focus of attention. A concierge in the very best hotel would never keep a guest waiting long for an answer; likewise, you should not keep your patients waiting.

Service: Concierges arrange service, where and when you want it. Likewise, in your aesthetic surgery practice, house calls or preoperative in-person checks on your patients who recover at home are appropriate, especially when patients may not want to be seen in public or have limited means to travel.

Accommodation: A concierge makes travel plans and helps travelers who are in unfamiliar territory. Patients may travel significant distances to see you, whether you are the closest geographic choice, are practicing in a choice destination, or are the preferred choice. Patients deserve assistance with travel arrangements for getting to, staying at, and enjoying your location. It is hospitable to do so.

Comfort: A concierge is the person to call with your special personal needs for comfort when traveling. Coordinating postoperative needs, whether these are for skin care, garments, amenities, or a place to recover, is good practice. It is inappropriate to perform a laser treatment on a client's skin, then send that person home with instructions stating, "Apply baking soda compresses and a coating of petroleum jelly for 4 days." Either provide the instructions far in advance so the patient can plan accordingly, or send the client home with the items he or she will need.

You may feel that concierge practices are excessive for most of your patients or are not right for your service model. Nevertheless, don't overlook the special needs some patients may have, and weigh the value of such services to your practice. Keep information on file for a concierge service that is willing to learn your business, understand your expectations, and serve your patients.

Retail

The goods that your practice sells must complement your services, but they also have some independent characteristics. Retail requires appropriate accounting and inventory, including the collection of sales tax. In some practices, retail goods are the only sale on which commissions can ethically be paid. They require an investment in inventory, typically carry a 100% markup, and necessitate close monitoring of inventory (as any retail function does) so that stock can be maintained appropriately for patient-client demand and be accounted for. Sales of retail products are enhanced by effective displays, but such items also attract theft. Products can also be sampled or tested, unlike the surgical procedures and services you provide.

Once clients use and are satisfied with retail items, the expectation is that they will continue to purchase them from you. This creates an ongoing revenue stream and brings the client back to your business regularly to purchase more. These repeat visits represent opportunities for maintaining the visibility of your other services.

Retailing in an aesthetic practice entails more than a patient's choosing a product; it requires that the physician or physician extender recommend the proper product to treat or prevent skin conditions, promote healing or healthy skin, prevent or reverse the effects of aging, and encourage renewal. Today even products sold in the drugstore tout these benefits and more. If you choose to carry retail items to satisfy your patients' needs, you should not sell a product unless you can confidently say that it is effective. If it is sold in a nearby drugstore or department store, make certain you can compete for dollars before you invest in inventory.

Retail can be a vital service complement and business component in an aesthetic practice, but for staff who sell or recommend products to patients, training is critical. Designate specific personnel to staff your retail operations; in some cases they will fulfill the retail function in addition to other roles. For the retail function to succeed, you must insist on staff training in product knowledge and sales technique. Putting products on the shelf and expecting that the client will ask about them is ineffective. Practitioners must find opportunities to recommend products. Sales support staff must expand on this recommendation and further recommend complementary products.

Skin Care

Your skin care choices must not be random selections; they must offer a reliable complement to your practice and its service menu.

Critical Elements of Skin Care

Exclusivity: Products must be those that can only be purchased through a physician.

Expectation: Products you sell must provide a distinctly better or different result from that of products purchased elsewhere.

Science: The research behind the product is consistent with medical research standards, testing, and approval.

Choose products based on the quality of their ingredients, packaging, texture, smell, and ability to stay fresh. Look for unique properties, clinically proven benefits, ease of use, safety, and established brand reputation with vendor support.

Rules of Retailing

Retailing skin care or other products that support your aesthetic surgery services is not as simple as stocking the shelves. Skin care, cosmetics, and at-home mechanical or light-based devices are valuable extensions to your practice, but they cannot sell themselves, and if they are misused or misguide your patients, they tarnish your image rather than creating value. Heed these caveats for in-house retail operations, a satellite medical spa, or an e-tailing operation:

Do not sell prescription-strength products unless you have a patient record, an in-office visit, and a prescription on file for the patient.

Do not sell products you are not familiar with or would not recommend to patients to treat a specific condition.

Do highlight products by problem and solution and by product type and brand, and do list complementary and conflicting products. There is no use selling someone something that results in distress instead of solutions.

Do highlight brands. Consumers look for recognized, well-known names.

Do collect data on those who purchase products from you. You'll want to know not only what they are buying from you, but also from other sources, with what frequency, and how they choose to mix and match. Most of all, you'll want to know when they stop buying, what they stop buying, and what they are asking for that you may not presently provide.

Financial Management

Financial planning and management are essential to any practice. These involve projecting income based on goals, related direct expenses, and overhead costs. Financial management of your practice requires understanding some core elements of finance: income and expenses. Income and expense decisions all factor in managing expectations that, on the most basic level, include your business's profitability, your personal income, the income and benefits you expect to provide to your staff (which may not be the same as what they expect to receive), and the service benefits your patients expect in exchange for what they are willing to pay.

Whether you are in an established, lucrative practice or one that is just beginning and is heavily leveraged, you must comprehend and participate in your financial planning. A plan in which you project, allocate, expense, adjust, and use all of these variables to set reasonable goals is the only means to control the practice's financial operations. To keep these details up-to-date and consistent with expectations, you will need an internal bookkeeper and outside advisors who may include an accountant, a banker, and an investment professional. Although you may trust your ac-

countant to tell you whether you can afford to invest in a new piece of equipment or a new facility, it is ultimately your decision, and you must understand the basic concepts of financial management.

ASSETS Your greatest asset—aside from your surgical training, skills, and certification—is the data you have on your patients and the relationship you have with those patients. Unfortunately, it’s rare that one can put a monetary figure on this asset. Most often assets are measured as tangibles that have worth; assets in your practice equate to property, equipment, and inventory (retail, drugs, and devices), your cash on hand, and the financial investments of the practice, such as retirement plans. Property, equipment, and inventory can all be financed, and they all can serve as collateral (used as security for financing these specific items or other endeavors). Assets in general can appreciate, as a retirement account would grow with interest income in a healthy economy. They can also depreciate, both for tax purposes and in terms of true worth. Technologies often depreciate quickly as they are replaced by newer and more powerful technologies. Tangible assets and your expectations for them are clearly defined on the balance sheet. But recognize too that you must manage your intangible assets—your clients and patients, referral relationships, and your image. While these don’t carry a dollar value that you can leverage, they do carry immense value that is essential to your success. Nurture and monitor your patient flow as carefully as you monitor your tangible assets.

CASH FLOW Cash flow is the amount of money you have on hand based on the income from services and what you must spend to stay in business on a daily basis. A healthy practice makes effective use of cash so you are never out of it, but also so you don’t have large amounts of cash on hand uninvested in your practice or in other lucrative ways.

DEBT Debt comprises the total of what you owe in principal, interest, penalties, on your line of credit, on credit cards, and even in utility bills and property taxes. Debt, like financing, may be short or long term.

LEVERAGING The concept of leveraging is simple: you borrow money to fund your practice or practice growth, planning that what the business makes will cover your investment and interest. Taking it one step further, leveraging also means that the cash you generate will also be enough to fund new endeavors, technologies, procedures, practices, or facilities in the ever-advancing world of cosmetic medicine. Short-term borrowing is for things with a low cost, potentially a short life, but a high cash return. Long-term borrowing is for things with a high cost, a long life, and a predictable return. Leasing is for things with a high cost, a short life, and a predictable return.

PROJECTIONS Generally tied to your tax cycle, projections are used to forecast what you might earn and spend in operating your practice. But projecting requires more than predicting your future based on the past year's taxes, or planning for the year ahead based on the outcomes of financial reports associated with your taxes. Projections must take into account your strategic plans for growth and what you must borrow, any necessary expense consolidation, economic cycles, risks, and new trends and opportunities. Projections are a forecast based on multiple factors, including the past, your knowledge of your patient base, and long-range adjustments in overhead.

Attempting to operate a practice in which nothing is predictable, with no plan or projections, will result not only in expectations that are unachievable, but also in a business that is unmanageable. Even if you practice simply for the love of what you do, you need to stay solvent.

The Importance of Planning

FOAD NAHAI

Despite our love of medicine and the challenge of surgery, operating an aesthetic surgery practice is a business, and issues of solvency, cash flow, and profitability must be addressed. You cannot operate a business that continuously loses money. Without a plan, you will likely find yourself with cash shortfalls and an inexplicable balance sheet, unable to succeed in focusing on what you do best: serving the needs of your patients.

All of this planning may seem a burden, and it is, but what is more burdensome is failing to plan and then looking for a reason to explain unmet goals. If history is documented as it is made, it is more factual, more effective, and more flexible. Fortunately, you don't have to be a financial wizard to do this, and you don't have to do it yourself. You and your partners can work together to define your tactical and fiscal goals and then work with a trusted accountant or financial advisor who can put it all together. As I have learned, the best way I can contribute to my practice is by maximizing my time providing service so the practice can succeed. Your reputation and that of your practice is built on the premise of your service, and you are an integral part of that "brand" and must help sustain it.

Tracking income and expenses is more than an accounting function—the empirical characteristic of financial matters allows you to make some important business decisions about how you practice. The accounting function also provides a basis on which to develop and revise policy, procedures, or pricing; identify losses and gains; and make valid business decisions.

Income

Income goals require that you understand how you make money, and how that money is used within your practice to pay for the items necessary to operate the business and to make your practice function. Patients will pay you by one or more of the means described next.

CASH Most staff are trustworthy and few actually steal, but the easiest thing to take without being noticed is cash. It's easy for an employee to avoid recording a transaction when a patient pays cash, or to hide cash paid for services with a low cost of treatment, such as procedures outside the operating room that need no clinical support, such as skin peels, microdermabrasion, waxing, and massage. Cash becomes an even greater liability when it is used to pay for skin care or cosmetics; if the employee pockets the money, you lose out on revenue as well as the value of your inventory. However, you cannot banish cash from your practice. Patients sometimes want to pay with cash for convenience, to avoid debt, or to avoid any trace of the transaction. If you recognize more or fewer transactions or an erratic cash flow over time, start looking for the cause.

CHECKS Personal checks are still a means of doing business, although they represent a much smaller portion of transactions today. The advantage of personal checks is that electronic banking now allows immediate deposit of funds into your account. The disadvantage is that if funds are not available in the patient's account, you will need to collect. This absorbs staff time, and it will cost you money while you wait to get paid or if you must go to collection. Establish a clear policy that fees are to be paid at the time of service and that deposits for surgery must clear days before the procedure. Define a collection policy for returned checks, or do not accept personal checks in your practice.

CREDIT AND DEBIT CARDS Convenience, rewards, travel miles, and financing are among the reasons a patient may use a credit card. These transactions add security for you as well as your customer, but they also come with a cost of doing business (fees to the credit card company).

Accepting payment by credit and debit cards is not foolproof. A too common situation, unfortunately, is that of an unhappy or debt-ridden patient who has been known to dispute charges in an effort to avoid paying. While this is in resolution, you don't get paid. With credit and debit cards, disputed charges represent a loss to your business. The easiest way to avoid disputes is to have a contract for services. But in aesthetic surgery, defining "return" procedures is not something you want to interject in managing your patient's experience. Enact security practices with credit cards: instruct your staff to discreetly pay attention to the name on the credit card, and match

signatures. Make certain all servers and connections where credit card and other personal information is stored are secure. It is naïve to think that there is no risk with credit and debit cards: identity theft is rampant, and your business may suffer if a scammer obtains your patients' personal credit card or private health care information. No matter how blameless you may be, a con artist who accesses a patient's or your private information will severely damage the patient's experience with your practice.

GIFT CERTIFICATES Selling gift certificates is big business. It allows either a non-surgical service or a specific dollar amount to be given. Laws regarding gift certificates or gift cards and their expiration vary from state to state. Never allow gift certificates to be issued for surgical procedures, and never limit gift certificates to a specific procedure—the recipient may not be interested or may not be an appropriate candidate, and as a result you will be viewed as restrictive, and the gift-giver will feel unappreciated.

PATIENT FINANCING Options in patient finance abound, and practices regularly offer financing programs to patients on high-ticket items such as surgery. But given the cost of doing business, administrative time, and fees paid, there is a value judgment to make in offering patient financing for fees in the hundreds rather than thousands of dollars. Surgeons who offer financing on relatively low-priced services are taking a big chunk out of their compensation; you should establish a minimum amount for financing. Set a limit or define a policy on when patient financing is offered and what it can be used for in your practice.

BARTER Quid pro quo is the oldest principle in business. You provide my skin care services, and I'll refer patients to you or promote your spa in my salon—there are many permutations of this. The question becomes: Does barter benefit the practice or the provider? Barter can be beneficial, because without collecting cash you are reducing taxable income. Although barter is easy, don't diminish the value of your services—barter for what they are worth. Set rules for barter so that each party is mutually benefiting, not one party benefiting at the other's expense. Proper accounting for barter is essential, or any analysis of your model will be flawed.

You must account daily for any income collected by the practice. A daily closing not only maintains balance, but also provides important tracking data. With daily closings you'll notice discrepancies sooner, such as cash transactions that are rapidly falling off. From daily closings you can chart the trend of your most productive days in procedures and product sales. From this you can also plan staffing more productively. And if you look closely, you might even determine whether busier days can

be attributed to more productive staff, or the trends in time your patients like to schedule services or make purchases.

Projecting income is essential to managing your practice. Unfortunately, although expenses can generally be detailed, budgeted, and allocated in a very defined manner, planning income is frequently overlooked and is not always easy to predict. Commonly, practices use a historical basis and apply a reasonable increase based on economic factors or projected growth to arrive at projected and budgeted income. Rarely is income budgeted and broken down in an aesthetic surgery practice as specifically as in other business segments. Why? It is not that this is unreasonable; it is just that it is not easy. You must project income based on the following:

Clinical service fees: Fees are broken down by reimbursed or insurance work, aesthetic surgery and aesthetic medicine, by service and provider. Surgery and anesthesia fees, if collected by your practice, should not be accounted with your practice's clinical service fees. These are facility and anesthesia fees, even if the anesthesiologist is an employee. Revenue generated by anesthesia is an adjunct, not direct revenue to your clinical fees.

Personal service fees: Aesthetician and other nonphysician, non-surgically generated revenue is broken down by service and by provider.

Retail: Retail income is budgeted by each brand and product.

Why is so much detail required? Before even applying direct expenses to each income line item, you will have an easy indicator of your greatest source of gross revenue. Then, once you apply direct expenses, you will have an indicator of all net revenue. Compare the two and see whether your highest gross revenue is also your highest net revenue producer. If not, you must review the direct expenses attached to that revenue producer to find out why a disparity exists. You can also use these factors to do the following:

Build growth on your greatest source of net income, your cash cows (this is easy logic).

Develop or retool those services where income and direct expense can improve (translate to cash cows).

Retool or eliminate services for which income and related direct expense result in a low net income. Retooling is valid if you can reasonably improve net income or if you cannot eliminate a service. Elimination of any service that yields a poor net income may mean a reduction of revenue, but it also allows an increase in productivity. In turn, this allows an increase in time commitment to the services that result in a better return.

In addition, budgeting income in such detail allows you to plan your direct expenses accordingly and maintain appropriate inventory.

Expenses

Expenses come in two specific streams: direct expenses and overhead. Direct expenses are relative to income. An increase in income or service may carry an increase in the expenses directly tied to providing service. For example, if you perform a breast augmentation, you will need the appropriate implants in inventory; the more breast augmentations you perform, the more implants you will need to purchase for inventory, which will increase your expenses. In a less direct equation, if you increase the income projections from personal services, such as clinical skin care, you must also account for the increase in related expenses, including all additional staff, supplies, and even the additional communication that will be necessary to grow that segment of your business. In greater detail, direct expenses include the following.

COST OF TREATMENT The cost of treatment includes single-use items for the cost of treatment such as breast or other implants, units of *Botulinum* toxin, syringes of dermal filler, and single-use packaged chemicals for peels; these are easy to allocate to each procedure performed. Technologic devices must also be considered a cost of treatment; however, how you allocate that cost is something only you can define based on the cost paid for the technology, the cost to operate it, and its depreciation.

GENERAL SUPPLIES General supplies include gauze, needles, cold packs, alcohol, gloves, and other disposables. It's difficult and time consuming to directly assign these costs to a treatment, so an estimate should be used to define a global supply cost to assign to treatments.

BACK BAR Back bar products include cleansers, volume chemicals, masques, massage oils, and skin care products used for treatments. These items cost you money and may be a source of waste or an easy target for theft, so it is essential to maintain an inventory and account for the use of all products. Either estimate a global cost to apply to each treatment, estimate a specific cost depending on the type of treatment, or include this as part of overhead, but in any case, attribute it to cosmetic medicine and keep an inventory.

COMPLIMENTARY TREATMENTS Whether testing a new treatment, providing treatments for staff, or as a thank-you or a touchup, complimentary treatments cost you something. Record this and compare what complimentary treatments cost you to the value they bring you. Complimentary treatments are an important part of demonstrating the value of treatments, creating walking billboards for treatments, testing new treatments, and showing goodwill or reward. I favor complimentary treatments far more than discounts for adding value.

DISCOUNTS Procedures must always be recorded for their full price; discounts must be recorded as an expense. You must have a measure of how much discounts truly cost your practice to determine whether they have value, such as generating increased sales.

Expenses also include what you pay providers and staff. There are multiple models of compensation, and combinations among the models.

HOURLY WAGES Wages are paid for time spent on-site, whether the individual is productively engaged in treatment or not. This is most often the least expensive model, but also the most likely to result in nonproductive time when disruptions to scheduling occur. If you pay hourly wages to providers of cosmetic medicine, make certain their job description includes duties to be undertaken when they are not actively performing treatments.

COMMISSIONS Commissions can be paid on product sales. It is unethical to pay a commission to someone who converts a patient to accept treatment. By doing so you would make a medical treatment a commodity; this is not a car, a stock sale, or a real estate transaction. Therefore you must not commission booking procedures. Higher commissions are typically paid for commission-only models; lower commissions are commonly coupled with hourly wages. Commissions can be individual or can be team based. Commissions can drive people to sell, to compete for sales, and to up-sell; that is, sell more than the patient was originally willing to buy. Carefully consider the relationship of commissions to your image and your client base and determine whether commissions create incentive and value, or pressure.

DIRECT PERCENTAGE OR SET FEES Direct percentage or set fees are more common with contractors than with employees. The provider receives a direct percentage of the revenues collected, or a set fee for specific treatments provided. Or the contractor may actually make the collections and pay you a direct percentage or a set fee.

OVERHEAD Overhead expenses are those incurred regardless of the pace of your business or income projections. These can be variable for many reasons. For instance:

Rent or mortgage is easily defined and likely unchanging in a yearly fiscal plan (unless you refinance or default on a payment and incur penalties).

Compensation of salaried employees and benefits to those employees are also easily defined and likely unchanging, although a rehire at a different compensation level or change in benefit plans could result in changes to overhead.

Insurance and utilities are easily defined and unchanging, unless you have a claim, the cost of utilities dramatically changes, or your utility consumption changes.

Taxes and interest expense are also defined as overhead, but they are not unchanging. Income changes, tax law changes, your write-offs change, the principal of your debt is paid down, you refinance, or you acquire more debt, and these all influence your overhead.

Projections and Overhead: Finding the Right Balance

FOAD NAHAI

Obviously, projections and your budget cannot always cover every contingency; there are always surprises that will be encountered in any practice. (Who could have imagined the breast implant crisis of 1992 or the recession of 2008/2009 and the impact these events had on plastic surgery practices?) However, a comprehensive set of projections taking the big picture into account will help you to weather unexpected blips in your forecasts.

Although one receptionist may be sufficient, a surgeon may choose to have an extra receptionist to provide better service and minimize telephone hold time. Similarly, a surgeon may choose to have a second nurse in the clinic to provide greater coverage when he or she is seeing patients. These extras are not essential but undoubtedly enhance the patient experience and make life easier for the surgeon. These “luxuries” come with a price, and the surgeon who is not aware of the finances of the practice can easily drive overhead to unacceptable heights. Similarly, an office-based surgicenter owned by the practice may also be looked at as a very expensive luxury. During a downturn, staff can be cut and operating rooms closed, but the tax, mortgage, or rent on the facilities remains unchanged. Although cutting staff may reduce costs, patient safety and the patient experience on which your practice has been built must not suffer.

There are countless examples of just how easily defined overhead expenses in an annual cycle can be variable, and how all of the variables tied to your business operations require a solid, detailed fiscal plan, including appropriate projections. So even though changes in direct expenses are theoretically relative to income and overhead is static, in reality, none of this is entirely predictable.

Limitations

Although few of us like to admit to limitations, we all have a maximum capacity as to what we can reasonably accomplish. Limitations include:

- Physical limitations to what you as a provider can physically accomplish
- Fiscal limitations to what you as a businessperson can economically manage
- Legal limitations defining requirements and limitations for you as a physician and businessperson

It is essential to your success and personal well-being that you recognize and accept the limiting factors that are outside your control while setting personal practice-defined limits that are within your control.

Physical Limitations

FOAD NAHAI

We all have physical limitations, even though our busy schedules would sometimes suggest otherwise. Few of us can deny the reality of what we feel after a day filled with surgery and seeing patients has concluded and we are still reviewing charts, writing chapters, preparing talks, working with PowerPoint, and planning our early-morning flight to present at a meeting in a remote location. Although it may seem glamorous, it can be exhausting.

Clearly, there are limits to what can be accomplished in any given period in providing service, managing the practice, meeting patient expectations, and fulfilling professional, educational, and organizational obligations. The goal is to expand the limits to be able to grow the practice without overtaxing your ability to manage this growth. This is best accomplished by finding other ways to add to growth and income that do not incur additional time commitments on your part and may even afford you some extra time to see more patients. These include adding support staff, adding services that expand your treatment options, hiring providers that complement your specialty (such as an aesthetician or dermatologist), and modifying facilities to provide more room for expanded services and activities.

Financial Limits

In any business there are always financial limits to consider. Even a seemingly “unlimited” cash flow has limits. Why spend something that will not generate a positive return for your practice? If your answer is merely because you want to and you have not done the groundwork to ensure that this contemplated expenditure will yield a benefit to your practice, then that purchase is not for the benefit or success of your practice; it is for your own personal benefit or pleasure.

A financial limit is simply the maximum a provider is able to or willing to spend on a given item. It is not how one overcomes financial limits that is essential to managing your practice; what influences your ability to succeed is how you approach financial limits, including allocations or adjustments of expenditures, or the demands you place on productivity or operations to maximize your return on those expenditures, and the adjustment of goals and objectives. In business there are three options for managing financial limits: borrowing, decreasing expenses, or increasing revenue.

BORROWING Will borrowing directly contribute to your success? Hardly. It will have an impact on your bottom line by requiring interest payments on debt. Although that is straightforward, borrowing will contribute to your success only if it includes well-reasoned related approaches to either decreasing expenses or increasing revenue through enhanced services, operations, image, or all of these things.

DECREASING EXPENSES How aesthetic plastic surgeons responded to the economic downturn that hit hard at the end of the past decade is proof that a practice can decrease expenses without affecting the patient experience. Decreasing expenses must be done in such a way that it does not damage outcomes. You can trim little bits all around, such as finding a more cost-effective supplier and rethinking utilities providers, insurance, or even your communications budget. The sum of a little can result in a lot of savings, but only if it does not diminish services, jeopardize the quality of care, or lead you to fall short of your goals. If you must take future steps, consider what is nonessential, or what is not fundamental to providing the services that produce your practice revenue.

Often the reaction is to find larger cuts rather than trim a little. For example, you may find a staff member or two who are paid more than the average for their positions. However, before you consider replacing one individual with someone else with a lower compensation range, consider the current employee's loyalty and the contributions he or she makes to serving the interests of patients. Can you risk the overall patient experience by bringing in an unknown person? What you reduce or what you spend must all be equated in value. If there is real value in an expense to your practice and trimming or cutting that expense will have a negative impact on your practice, you must make a value judgment. Manage your expectations with those of your patients; decreasing expenses to meet your needs, but falling short on meeting your patients' needs, may cost you far more than you ultimately could expect to save.

INCREASING REVENUE The third option for addressing financial limits is increasing revenue. Will a slight increase in fees affect services or traffic? Can productivity be enhanced to make more time for billable service, and if so, how might this affect quality of care? Can conversion or retention be improved? Can traffic be increased? What will any of these things cost to accomplish? Increasing revenue should reflect the success of your practice, but only when it is relative to the effort and expense necessary to do so, and when it does not have an impact on what your patients expect of you.

When you determine how you will approach your financial limitations, you need to adjust your goals and strategic, financial, and applied plans. Define what you will do to address and resolve your financial limitations in your strategic plan. Revise your budgets and projections accordingly. Track all that you do along the way and

the resulting impact on your practice. Unless you do this, you will not know if your approach was correct or where it may have faltered or failed you. Make adjustments and corrections, and continue to manage the situation.

Concluding Thoughts

Managing a practice is a challenging but rewarding endeavor. Effective staff management and careful fiscal planning are key to producing a well-run and profitable practice. Obviously, the surgeon's skill and reputation is the foundation of any practice, but this must be supplemented and complemented by a staff that is well trained, loyal, responsive to patient needs and expectations, and attuned to quality. With the right systems in place, a carefully thought out menu of services, a trained and responsive staff, and the appropriate fiscal controls, a practice can respond to changing trends and provide a solid platform for future growth.

Clinical Caveats

Managing expectations is key to managing your practice. Managing the patient experience comes first; but your expectations, the expectations of those you employ and even of your community, along with the very real expectations of your family all must be managed, every day. The principles, practices, and strategies of managing, staff, services, and finances are essential to managing your operation. But to truly succeed, you need to do more than simply follow the path where the aesthetic surgery and service industry meet; you must navigate that path daily, implementing these essential concepts:

- *Goals:* Short or long term, narrow or broad, you need goals. Goals for revenue are fundamental, goals for your time, your staff, efficiencies, patient satisfaction or retention, growth, continuing education, even goals for self-enrichment give you a target on which to set your sights and attain. At a minimum, pen a set of goals and review and revise them annually. At an optimum, each day define a new goal, or revisit and refine just one of the goals on your agenda.
- *Quality:* Perfection is an absolute: once you attain perfection you can only plateau, or, as the world around you moves and changes, potentially you may slide. Strive for quality—giving your best, being the best, expecting the best, and encouraging it. Quality does not always require great expense, but it does require attention to detail, care, and respect.

Continued

Clinical Caveats—cont'd

- *Consistency*: Every day is a new day, every patient a new case, every challenge a new opportunity to succeed. The variables and people within your practice are diverse. So that you do not lose site of your goals or jeopardize quality, your approach and expectations must be consistent. Define who you are, what your patients and you expect, and be unswerving in how you go about delivering your service.
- *Flexibility*: Rigid people, practices, and policies have no room to “give.” In a dynamic world, you must be flexible and sensible. However, stretching has its limits; reach too far and you risk injury. Set policies, rules, and boundaries, and within them, allow for the flexibility necessary to achieve your goals while maintaining quality and consistency.
- *Balance*: In your aesthetic practice, strive for harmony in more than the results of your surgical skill. Your practice may be the dominant force in your life, but it is not and must not be the only thing that rules your world. Find balance between your practice and your life outside your practice. Family, friends, interests, and passion for someone or something other than your patients will help you to appreciate the goals you have set for yourself, the quality exemplified within your practice, and the rewards it brings you in income and satisfaction.

CHAPTER 8

Aesthetic Surgery and the Law

MARK GORNEY

It is unfortunate that during the lengthy process of postgraduate surgical education, the vast majority of candidates for certification by the American Board of Plastic Surgery, as well as candidates in otolaryngology, oculoplastics, and dermatology, fail to fully grasp the relationship between aesthetic surgery and psychiatry. Virtually all such candidates emerge into the clinical world filled with knowledge of the latest cutting edge techniques in their specialty, but with only the vaguest sense of the critical importance of appropriate patient selection criteria in elective surgery, the *sine qua non* of building a successful career.

The problem is further compounded by several factors. The first is the love affair between the media and the universe of beauty surgery. The barrage of publicity surrounding new techniques and procedures is inevitably accompanied by promises of improvements as dramatic as they are trouble free. The second issue is the unfortunate decision by the U.S. Federal Trade Commission, which in the late 1980s enforced an end to the traditional prohibition of advertising by physicians. This, added to the fact that aesthetic surgery presents to many practitioners the promise of hassle-free additional income, further confuses the definition of adequate surgical training qualifications and quickly adds a carnival atmosphere to the practice of aesthetic surgery.

Mental health professionals and aesthetic surgeons agree that patients who exhibit signs that suggest a variety of psychiatric diagnoses are very poor candidates for any elective surgery. But some disorders, such as body dysmorphic disorder (BDD), come in many shades of gray. This compounds the difficulty for a surgeon who is not familiar with warning signs that may seem reasonably obvious to a psychologist.

To confuse matters even more, experienced plastic surgeons can recall patients in their practices whose minimal to moderate deformities caused disproportionate patient concern, yet after a well-executed correction, they experienced positive personality and life changes.

So what should the surgeon's appropriate response be when faced with a patient who seems to have an excessive preoccupation with a very slight or imagined deformity? Learning to say "No" may sound easy, but it is far more complicated than it appears (see Chapter 1). Referral to a psychiatrist or psychologist almost always results in an angry patient who walks out and will, sooner or later, have the procedure done anyway (and will reap the consequences). The only reasonable course left to the surgeon is to learn as early in his or her career as possible to select among those shades of gray and where uncertainty exists and to rely on the counsel of more experienced plastic surgeons or psychiatric colleagues, regardless of the consequences. Failure to do so produces problems for the surgeon far beyond the value of any surgical fee. In its ultimate (but thankfully rare) form, ignoring the "red flag" warnings has cost at least five surgeons their lives in the past two decades: all were shot to death by disturbed patients dissatisfied with their results.

To those whose primary responsibility is the maintenance of the highest quality in surgical competence and to the risk managers in the professional liability world, all the continuous dramatic changes in surgical technology have added an ever-growing challenge and an increasingly heavy burden. However, none of these technologic advances should change the essential criteria for appropriate patient selection. In observing these criteria it is impossible to avoid occasional incursions into the domain of mental health professionals.

Of all medical specialists, the plastic surgeon's exposure to professional liability is unique in several respects:

1. The plastic surgeon who performs elective aesthetic surgery is not assuming the care of a sick or injured patient to make him or her well; rather, it is a matter of taking a well patient to make him or her better.
2. The patient judges the results of treatment according to standards that are entirely subjective, and often colored by the patient's self-image. The actual result may be good, but if it does not meet the patient's expectations, it may be judged a failure.

After years of practicing, teaching, and evaluating claims against plastic surgeons, I have concluded that the four most critical elements for successful plastic surgery are these:

1. Competence
2. Appropriate patient selection criteria
3. Documented disclosure
4. True informed consent

The remainder of this section will describe the plastic surgeon's obligation to the patient and review in some detail the medicolegal parameters that apply. My primary purpose is to provide an overview of the significant interface between elective aesthetic surgery and the specter of medical liability.

Legal Principles Applied to Plastic Surgery

Standard of Care

Malpractice generally means treatment that is contrary to accepted medical standards and that produces injurious results in the patient. Most medical malpractice actions are based on laws governing negligence. Thus the cause of action is usually the failure of the defendant/physician to exercise that reasonable degree of skill, learning, and care ordinarily possessed by others of the same profession in the community. Whereas in the past the term *community* was accepted geographically, it is now based on the supposition that all physicians keep up with the latest developments in

their field. Thus community is now generally interpreted as a *specialty community*; the standards are those of the specialty as a whole without regard to geographic location. This series of norms is commonly referred to as the *standard of care*.

Warranty

The law holds that by merely engaging to render treatment, a physician warrants that he or she possesses the learning and skill of the average member of that specialty and will apply that learning and skill with ordinary and reasonable care. This warranty is one of *due care*. It is legally implied; it need not be mentioned by the physician or the patient. However, the warranty is one of service, not of cure. Thus the physician does not imply that the operation will be a success, or that results will be favorable, or that he or she will not commit any medical errors not caused by lack of skill or care.

Disclosure

While attempting to define the yardstick of disclosure, the courts divide medical and surgical procedures into two categories:

1. Common procedures that carry minor or very remote serious risk (including death or serious bodily harm); for example, the administration of antibiotics
2. Procedures involving serious risks for which the physician has an affirmative duty to disclose the potential of death or serious harm and is obligated to explain in detail the complications that could possibly occur

Affirmative duty means that the physician must disclose risks on his or her own, without waiting for the patient to ask. The courts have long held that it is the patient, not the physician, who has the prerogative of determining what is in his or her best interests. Thus the surgeon is legally obligated to discuss with the patient therapeutic alternatives and their particular hazards to provide sufficient information to allow the patient to determine what is in his or her own best interest.

How much explanation and in what detail are dictated by a balance between the surgeon's feelings about the patient and the applicable legal requirements. It is simply not possible to tell patients everything without unnecessarily dissuading them from appropriate treatment. Rather, the law holds that patients must be told the most probable of known dangers and the percentage of likelihood of an adverse result. More-remote risks may be disclosed in general terms, but at the same time comparing their likelihood of occurring with everyday, unexpected events with unpleasant outcomes. Do patients have the legal right to make bad judgments because they fear a possible complication? Increasingly, the courts answer affirmatively. Once the information has been fully disclosed, that aspect of the physician's obligation has been fulfilled. The weighing of risks is usually not a medical judgment but is instead reserved for the patient.

Obviously, the most common complications should be volunteered frankly and openly, and their probability, based on the surgeon's personal experience, should also be discussed. Finally, any or all of this information is wasted unless it is documented in the patient's record. For legal purposes, if it is not in the record, it never happened!

Informing Your Patients Before They Consent

“Prudent Patient” Test

In many states the most important element in claims involving disputes over informed consent is the prudent patient test. The judge will inform the jury that there is no liability on the physician's part if a prudent person in the patient's position would have accepted the treatment had he or she been adequately informed of all significant perils. Although this concept is subject to reevaluation in hindsight, the prudent patient test becomes most meaningful where treatment is lifesaving or urgent.

The concept may also apply to simple procedures in which the danger is commonly thought to be remote. In such cases disclosure need not be extensive, and the prudent patient test will usually prevail.

Refusals

As part of medical counseling, many state laws mandate that physicians warn patients of the consequences of failing to heed medical advice by refusing treatment or diagnostic tests. Obviously, patients have a right to refuse. In such circumstances it is essential that such refusals and their consequences be carefully documented and that the surgeon verify and document that the patient understood the consequences.

Documentation is particularly important in cases involving malignancy, where rejection of tests may impair diagnosis and refusal of treatment may lead to the patient's death. It is important to date all such entries in the patient record.

If the information you present includes percentages or other specific figures that allow the patient to compare risks, be certain that your figures conform to the latest reliable data.

Consent-in-Fact and Implied Consent

What is the distinction between ordinary consent to treatment (consent-in-fact) and informed consent? Simply stated, informed consent verifies that the patient is aware of anticipated benefits as well as risks and alternatives to a given procedure, treat-

ment, or test. On the other hand, proceeding with treatment of any kind without actually obtaining consent is “unlawful touching” and may therefore be considered *battery*.

When the patient is unable to communicate rationally, as in many emergency cases, there may be a legally implied consent to treat. The implied consent in an emergency is assumed only for the duration of that emergency.

Treating Minors

Except in urgent situations, treating minors without consent from a parent, legal guardian, appropriate government agency, or court carries a high risk of legal or even criminal charges. There are statutory exceptions, such as for an emancipated adolescent or a married minor. If you regularly treat young people, you should familiarize yourself with the existing statutory provisions in your state and keep up to date.

Religious and Other Obstacles to Treatment

Occasionally you may be placed in the difficult position of being refused permission to treat or conduct diagnostic tests on the basis of a patient’s religious beliefs or personal convictions. Although grave consequences may ensue, there is little you can do in most states, beyond making an intense effort to convince the patient to undergo the tests or treatment. In some states, court intervention may be obtained. Here too, knowing the law of the state in which you practice is advisable. In all cases the informed refusal must be carefully documented.

If a patient is either a minor or incompetent (and the parent or guardian refuses treatment for the patient) and you know serious medical consequences will ensue if appropriate tests and/or treatment are not undertaken, your legal and moral obligations change. You must then resort to a court order or another appropriate governmental process in an attempt to secure surrogate consent. The participation of personal or hospital legal counsel is advisable to ensure that the legal requirements applicable in your locale are met.

The Six Elements of Informed Consent

In situations in which treatment is urgent (for example, in a patient with severe trauma), it may be needless and cruel to engage in extensive disclosure that could add to existing anxieties. However, you should inform the patient (or the closest relative or guardian) fully and completely of the treatment’s risks and consequences

and document such discussions. The following six elements of a valid informed consent fulfill what the law requires:

1. The diagnosis or suspected diagnosis
2. The nature and purpose of the proposed treatment or procedure and its anticipated benefits
3. The risks, complications, or side effects
4. The probability of success, based on the patient's condition
5. Reasonable available alternatives
6. The possible consequences if advice is not followed

In situations in which the nature of the tests or treatment is purely elective, as with cosmetic surgery, the disclosure of risks and consequences may need to be expanded. Literature available in the surgeon's office can provide additional details about the procedure. In addition, an expanded discussion should take place regarding the foreseeable risks, possible untoward consequences, or unpleasant side effects associated with the procedure. This expansion is particularly necessary if the procedure is new, experimental, especially hazardous, capable of altering sexual capacity or fertility, or *purely* for cosmetic purposes.

Documentation

Written verification of consent to diagnostic or therapeutic procedures is crucial. A simple entry of several lines might suffice, such as: "Have discussed in detail objectives, technique, and potential complications of procedure. Have also discussed location and possible appearance of scars and sources of dissatisfaction. All questions answered. Patient understands and accepts."

Also remember, however, that in an increasing number of circumstances laws now require the completion of specifically designed consent forms. Studies indicate that physicians sometimes actually *underestimate* the patient's ability to understand. If your records disclose no discussion or consent, the burden will be on you to demonstrate legally sufficient reasons for such an absence. It is a test of your good judgment of what to say to your patient and of how to say it to obtain meaningful consent without frightening the patient. No permit or form will absolve you from responsibility if there is negligence, nor can a form guarantee that you will not be sued. Permits may vary from simple to incomprehensibly detailed. Most medicolegal authorities agree that a middle ground exists.

A well-drafted informed consent document is proof that you tried to give the patient sufficient information on which to base an intelligent decision. Such a document, supported by a handwritten note and entered in the patient's medical record, is often the key to a successful malpractice defense when the issue of consent to treatment arises.

The Therapeutic Alliance

Obtaining informed consent need not be an impersonal legal requirement. When properly conducted, the process of obtaining informed consent can help establish a “therapeutic alliance” and launch or reinforce a positive physician-patient relationship. If an unfavorable outcome occurs, that relationship can be crucial to maintaining patient trust.

A patient’s usual psychological defense mechanism against uncertainty is to endow his or her physician with omniscience in the science of medicine—an aura of omnipotence. By weighing how you say something more heavily than what you say, you can turn an anxiety-ridden ritual into an effective claims-prevention mechanism. Psychology literature refers to this as the *sharing of uncertainty*. Rather than shattering a patient’s inherent trust in you by presenting an insensitive approach, your dialog should be empathetic to the patient’s particular concerns or tensions and should project believable reactions to an anxious and difficult situation.

Consider, for example, the different effects that the following two statements would have:

- “Here is a list of complications that could occur during your treatment [operation]. Please read the list and sign it.”
- “I wish I could guarantee you that there will be no problems during your treatment [operation], but that wouldn’t be realistic. Sometimes there are problems that cannot be foreseen, and I want you to know about them. Please read about the possible problems, and let’s talk about them.”

By using the second statement, you can reduce the patient’s image of you as omnipotent to that of a more realistic and imperfect human being, who is facing, and thus sharing, the same uncertainty. The implication is clear: “We—you and I—are going to cooperate in doing something to your body that we hope will make you better, but you must assume some of the responsibility.”

To allay anxiety, you may seek to reassure your patients. However, in so doing, be wary of creating unwarranted expectations or implying a guarantee. Consider the different implications of these two statements:

1. “Don’t worry about a thing. I’ve taken care of hundreds of cases like yours. You’ll do just fine.”
2. “Barring any unforeseen problems, I see no reason why you shouldn’t do very well. I’ll certainly do everything I can to help you.”

If you use the first statement and the patient does not “do fine,” he or she is likely to be angry with you. The second statement gently deflates the patient’s fantasies to realistic proportions. This statement simultaneously reassures the patient and helps him or her to accept reality.

The therapeutic objective of informed consent should be to replace some of the patient's anxiety with a sense of his or her participation with you in the procedure. Such a sense of participation strengthens the therapeutic alliance between you and your patients. Instead of seeing each other as potential adversaries if an unfavorable or less than perfect outcome results, you and your patients are drawn closer by sharing acceptance and understanding of the uncertainty of clinical practice.

Patient Selection Criteria

Contemporary plastic surgeons practicing in the United States will find it virtually impossible to end their careers unblemished by a claim of malpractice. However, well over half of these instances are preventable. Most are based either on failures of communication or patient selection criteria, not on technical faults.

Patient selection is the ultimate inexact science. It is a mixture of surgical judgment, gut feelings, personality interactions, the surgeon's ego strength, and regrettably, economic considerations. Regardless of technical ability, a surgeon who appears cold, arrogant, or insensitive is more likely to be sued than one who relates at a personal level. Obviously, a person who is warm, sensitive, naturally caring, and has a well-developed sense of humor and cordial attitude is less likely to be the target of a malpractice claim. The ability to communicate clearly is probably the most outstanding characteristic of the claims-free surgeon. Communication is the *sine qua non* of building a physician-patient relationship. Unfortunately, the ability to communicate well is a personality characteristic that cannot be readily learned in adulthood. It is an integral part of the surgeon's personality. There are, however, a number of helpful guidelines.

GREAT EXPECTATIONS There are certain patients who have an unrealistic and idealized yet vague conception of what elective aesthetic surgery is going to achieve for them. They anticipate a major change in lifestyle, with immediate recognition of their newly acquired attractiveness. These patients may have an unrealistic concept of where their surgical journey is taking them and have great difficulty in accepting the fact that any major surgical procedure carries inherent risk.

THE EXCESSIVELY DEMANDING PATIENT In general, the patient who brings photographs, drawings, and exact "architectural" specifications should be managed with great caution. Such a patient may have little comprehension that the surgeon cannot sculpt human flesh and blood as one would clay or marble. The patient must be brought to understand the realities of surgery, the vagaries of the healing process, and the margin of error that is a natural part of any elective procedure. Such patients show very little flexibility in accepting any failure on the part of the surgeon to deliver what was anticipated.

THE INDECISIVE PATIENT To the question, “Doctor, do you think I ought to have this done?” the prudent surgeon should respond, “That is a decision I cannot make for you. It is one you have to make yourself. I can tell you what I think we can achieve, but if you have any doubt whatsoever, I recommend strongly that you think about it carefully before deciding whether or not to accept the risks which I have discussed with you.” The more the decision to undergo surgery is motivated from within and not “sold,” the less likely that recriminations will follow an unfavorable result.

THE IMMATURE PATIENT An experienced surgeon should assess not only the physical maturity but also the emotional maturity of the patient. A youthful or immature patient (age has no relationship to maturity) usually has highly unrealistic expectations of what the surgery will achieve. When confronted with a mirror postoperatively, this type of patient is likely to react in disconcerting or even violent fashion if the degree of change achieved does not coincide with their preconceived notions.

THE SECRETIVE PATIENT Certain patients want to convert their surgery into a “secret” and request elaborate precautions to prevent anyone from knowing they are having surgery. Aside from the fact that such arrangements for secrecy are difficult to achieve, this tendency is a strong indication that the patient has a degree of guilt about the procedure. Thus there is a higher likelihood of subsequent dissatisfaction.

FAMILIAL DISAPPROVAL It is far more comfortable, although not essential, if the immediate family approves of the surgery being sought, particularly in the case of a minor. If there is disapproval, errors in communication or less than optimal results, this produces an automatic “See, I told you so!” reaction, which deepens the patient’s guilt as well as dissatisfaction.

PATIENTS YOU DON’T LIKE (OR WHO DON’T LIKE YOU) Regardless of the surgeon’s personality, in life there are people you simply don’t like or who don’t like you. Most experienced surgeons know within minutes of entering the examining room whether they will or will not be operating on that patient. Accepting a patient whom you basically dislike is a serious mistake. A clash of personalities, for whatever reason, is bound to affect the outcome of the case, regardless of the actual quality of the postoperative result. No matter how “interesting” such a case may appear, it is far better to decline the patient.

THE “SURGIHOLIC” A patient who has had a variety of plastic surgery procedures performed and who might be called a *surgiholic* often is attempting to compensate for a poor self-image by undergoing repeated surgeries. In addition to the implications of

such a personality pattern, the surgeon is also confronted with a more difficult anatomic situation as a result of the previous surgeries. He or she also risks unfavorable comparison with previous surgeons. Often the percentage of achievable improvement isn't worth the risk of the procedure.

An experienced surgeon is generally aware that patients often try to conceal their true motivation for surgery. This can be a minefield for the surgeon and can result in far-reaching, unpleasant end results.

Generally speaking, there is a clear risk-benefit ratio to every surgical procedure. If the risk-benefit ratio is favorable, the surgery should probably be encouraged and has a high probability of success. If the risk-benefit ratio is unfavorable, the reverse not only applies, but also the unintended consequences of the unfavorable outcome may turn out to be disproportionate to the surgical result. The only way to avoid a debacle is to learn how to distinguish those patients whose body image and personality characteristics make them unsuitable for the surgery that they seek.

The Wheel of Misfortune: Exposures Most Likely to Generate Claims

It should come as no surprise that the overwhelming majority of malpractice claims lodged against plastic surgeons are concentrated in a handful of aesthetic surgery operations. Unlike other surgical specialists, the plastic surgeon attending a patient who seeks aesthetic improvement is not trying to make a sick patient well, but rather a well patient better. This not only places a much heavier burden of responsibility on the operating surgeon, but also subjects him or her to a much broader range of possible reasons for patient unhappiness. Sources of dissatisfaction can range from a catastrophic result to something as unpredictable as a patient's hidden emotional agenda or a simple communications failure.

Competitive pressures in the last few years have also blurred strict criteria for patient selection. As a result, it is not surprising to see a steadily upward trend in the frequency of claims against plastic surgeons. We have surveyed approximately 1000 plastic surgeons about the genesis of patient complaints across 15 years' experience. Losses from lawsuits against plastic surgeons are notable for their frequency rather than their severity (a large number of claims alleging relatively minor damages). Although severity has never characterized plastic surgery's loss experience in the past, the clear trend is toward ever-larger awards, particularly in cases in which an elective procedure has resulted in a patient's death.

Data from TDC, Napa, CA: 2009.

A pie chart shows the distribution of aesthetic surgery claims in our practice in 2009.

Scarring

Most surgeons assume the patient understands that healing involves the formation of scar. Unfortunately, this is seldom discussed in the preoperative consultation. In plastic surgery, the appearance of the resulting scar can be the major source of dissatisfaction. It is imperative that the plastic surgeon obtain from the patient clear evidence of his or her comprehension that without a scar, there is no correction and no healing. The patient must be made to understand that his or her healing qualities are as individual as hair texture or eye color; they are built into each person's genetic program. Documentation of such a conversation in the preoperative chart should go a long way toward making any resulting claim more defensible.

Breast Reduction

The genesis of dissatisfaction most often involves:

- An unsatisfactory scar
- Loss of nipple or breast skin cover requiring revision
- Asymmetry or "disfigurement"

Breast Augmentation

Litigation involving breast augmentation is even more common than with breast reduction surgeries. Approximately 44% of all elective surgery claims involve augmentation. Setting aside for the moment breast implants and autoimmune disease, the most frequent causes of dissatisfaction are:

- Encapsulation with distortion and firmness
- Wrong size (too small, too large)

Infection

The need for repeat surgeries and their attendant costs

Nerve damage with sensory loss

Face Lift and Blepharoplasty

Face lifts and blepharoplasties account for approximately 11% of all claims. The most common allegations are:

Excessive skin removal, resulting in a “starey” look

Dry eyes or the inability to close the eyes

Nerve damage, resulting in a distorted expression

Skin slough, resulting in excessive scarring and the need for revision surgery

Impaired vision

The most dreaded complication in blepharoplasty is permanent impairment of sight. A few years ago, while reviewing a series of five such cases with no evident causation, we suddenly discovered a common thread: in all five patients the operation had been conducted with a local anesthetic containing added epinephrine. All patients had been sent home with less than 60 minutes of recovery time. All had done something after returning home that caused a sudden rise in blood pressure: a sneezing fit, nausea, a constipated bowel movement. This was followed shortly thereafter by orbital pain and massive ecchymosis requiring emergency evacuation of a periorbital hematoma. These problems are difficult; some patients fully or partially regain vision. All require the attention of an ophthalmic surgeon.

Rhinoplasty and Septoplasty

Lawsuits associated with rhinoplasty and/or septoplasty procedures constitute approximately 15% of aesthetic claims. Among the most common allegations are:

Unsatisfactory result: improper performance

Continued breathing difficulties

Asymmetry

Of all operations performed by plastic surgeons, rhinoplasty and septoplasty have the highest degree of unpredictability. The problem is greatly exacerbated by inappropriate patient selection criteria. In these claims there is almost universally a gap between the patient's expectations and the results obtained, even when the surgical outcome appears excellent. The inappropriate use of imaging devices very often causes patients to have unrealistic expectations, as does the showing of “brag books” containing only excellent results. The clear implication is: “This is the kind of work that I do, and this is what you can expect.” Unfortunately, in many cases the actual results fall short of the promise, and a cycle of dismay and disappointment is put into motion.

It is interesting to note that the incidence of dissatisfaction in rhinoplasty is more than twice as common in men as it is in women.

Abdominoplasty

Abdominoplasty with or without suction-assisted lipectomy represents approximately 3% of claims. The most common allegations are:

- Skin loss with poor scars
- Nerve damage
- Inappropriate operation
- Infection with postoperative mismanagement

There is little question that the combination of suction-assisted lipoplasty before the actual abdominoplasty has significantly increased the morbidity rate associated with this operation and doubled the number of claims in this category. Clearly, a much higher percentage of skin sloughs occur in procedures preceded by suction-assisted lipectomy.

Suction-Assisted Lipectomy

Suction-assisted lipectomy procedures, whether conventional or ultrasonic, have now become the single most requested elective aesthetic procedure in the United States. However, the rising popularity of this procedure has brought with it a host of problems. To begin with, because this is not a surgical procedure in the traditional sense, it is being performed by a wide variety of practitioners, some of them with no surgical

background or clear understanding of the surgical anatomy involved. Additionally, with the advent of “tumescent” techniques, an unseemly race has developed to see who can suction out the most fat. The net result has been a dramatic rise in severe morbidity and fatal outcomes from “high-volume” liposuction. What is high volume? It is generally agreed that anything above 5000 cc of extracted fat constitutes high volume. The extraction of this amount of fat causes profound physiologic changes, which in turn can lead to severe complications and/or fatal outcomes. Also, the infusion of large amounts of fluid with even a weak concentration of lidocaine has also resulted in a number of fatal outcomes as a result of anesthetic overdose.

To make matters worse, these procedures are often combined with other prolonged operations. Our experience clearly indicates that when a patient has been under anesthesia for more than 6 hours, undergoing multiple procedures, the percentage of complications and/or fatal outcomes rises dramatically.

The cavalier way in which this operation is sometimes performed requires rethinking, particularly when the amounts of fat extracted are significant. In a number of venues in the United States, the state medical regulatory authorities are beginning to take notice, and unless there is a significant downturn in the morbidity associated with this procedure, there will undoubtedly be some regulatory intervention.

Skin Resurfacing

Chemical peels and laser resurfacing constitute roughly 3% of lawsuits. The principle allegations are:

- Blistering/burns with significant scarring
- Infection/postoperative mismanagement
- Permanent discoloration postoperatively

Because individual healing characteristics are unpredictable, it is probably a good idea to do a “test patch” in an area that can be hidden (for example, the back of the neck). Certainly the printed information given to the patient preceding this operation should contain clear warnings that the quality of healing is linked to the individual’s genetic makeup and cannot be predicted. The operator must make it clear to the patient that final color and texture determination is not always in the hands of the surgeon, and heavy makeup may be needed for an indeterminate period.

Miscellaneous Claims

Approximately 5% of all complaints against plastic surgeons have to do with miscellaneous allegations, such as:

- Untoward reaction to medications or anesthesia
- Improper use of preoperative or postoperative photos
- Sexual misconduct (physician or employee)

There are certain common issues among all procedures performed by plastic surgeons that are commonly not brought to the attention of the patient in preoperative consultations, yet often are the triggering mechanism for a claim. They are:

- Unexpected scarring
- Lack of adequate disclosure (tailored to the patient's level of understanding)
- General dissatisfaction: the patient's expectations were not met

Psychological and Psychiatric Aspects of Modifying Anatomy

The increasing popularity of elective aesthetic surgery makes it imperative to establish clear criteria for patient selection. Who is the “ideal” candidate for aesthetic surgery? The surgeon must differentiate between healthy and unhealthy reasons for seeking aesthetic improvement.

There are basically two categories that make the patient a poor candidate for elective aesthetic surgery. The first is anatomic unsuitability, but the second is equally important, though more subtle: psychological inadequacy. The strength of a patient's motivation is critical: it has a startlingly close relationship with the patient's satisfaction postoperatively. Furthermore, a strongly motivated patient tends to have less pain, a better postoperative course, and a significantly higher index of satisfaction.

Although these characteristics are impossible to predict with absolute accuracy, it is possible to establish some objective criteria for patient selection. These are illustrated in the graph above.

A patient's objective deformity can be depicted along the horizontal axis (as judged by the surgeon), while the degree of concern over that deformity (as perceived by the patient) can be represented on the vertical axis. Two opposite extremes emerge:

1. A patient with a major deformity but minimal concern is represented in the lower right-hand corner. This is a patient with an obvious major deformity in whom it is clear that any degree of improvement will be regarded with satisfaction.
2. A patient with a minor deformity but extreme concern is represented in the upper left-hand corner. In contrast, this is a patient with a deformity that the surgeon perceives to be minor, but who demonstrates an inordinate degree of concern and emotional turmoil. Such patients are most likely to be dissatisfied with any outcome. The anxiety expressed over the "deformity" is merely a manifestation of inner turmoil, which is better served by psychiatric care than by a surgical procedure.

Most persons who seek aesthetic surgery fit somewhere between the two. The closer the patient comes to the upper left-hand corner of the graph, the more likely that surgery will result in an unfavorably perceived outcome, and possibly involvement of a lawyer.

Effective Communication

Most litigation in plastic surgery has the common denominator of poor communication. This physician-patient relationship can be shattered by the surgeon's arrogance, hostility, coldness (real or imagined), or simply by the fact that "he or she didn't care." There are only two ways to avoid such a debacle: (1) make certain that the patient has no reason to feel that way, and (2) avoid treating a patient who is going to feel that way no matter what is done.

Although the physician's skill, reputation, and other intangible factors contribute to a patient's sense of confidence, rapport between the patient and physician is based on forthright and accurate communication. This will normally prevent the vicious cycle of disappointment, anger, and frustration by the patient, and reactive hostility, defensiveness, and arrogance from the physician, which deepens the patient's anger and ultimately may provoke a lawsuit.

Anger: A Root Cause of Malpractice Claims

Patients feel both anxious and bewildered when elective surgery does not go smoothly. The borderline between anxiety and anger is tenuous, and the conversion factor is uncertainty—fear of the unknown. A patient frightened by a postoperative complication or uncertain about the future may surmise: "If it is the doctor's fault, then the responsibility for correction falls on the doctor."

The patient's perceptions may clash with the physician's anxieties, insecurities, and wounded pride. The patient blames the physician, who in turn becomes defensive. At this delicate juncture, the physician's reaction can set in motion a chain reaction—or prevent one. The physician must put aside feelings of disappointment, anxiety, defensiveness, and hostility to understand that he or she is probably dealing with a frightened patient who is using anger to gain control of the situation.

The patient's perception that the physician understands that uncertainty, and will join with him or her to help to overcome it, may be the deciding factor in preserving the therapeutic relationship.

One of the worst errors in dealing with an angry or dissatisfied patient is to try to avoid the patient. The surgeon must actively participate in the process rather than attempting to avoid the issue.

Body Dysmorphic Disorder (BDD)

As the popularity of aesthetic surgery increases, one is reminded of the fairy tale in which it is asked: "Mirror, mirror, on the wall, who's the fairest of them all?" The number of patients finding comfort and solace in multiple elective surgical procedures is growing. Beyond the unrealistic expectations of aesthetic correction, many patients seek surgery when the need for it is dubious at best. The physical change sought through surgery is usually more a manifestation of the patient's flawed body image or preoccupation with a perceived flaw than of a measurable deviation from physical normality. Beware of the patient showing a pathologic preoccupation about a physical trait that may be within normal limits or so insignificant as to be barely noticeable, but that to the patient has become a consuming obsession.

The trend toward vigorous advertising and marketing of cosmetic surgery continues to grow worldwide, and in such a climate there is a greater probability that individuals with BDD will eventually opt for the surgeon's scalpel rather than a psychiatrist's consultation as an answer to their perceived problem. Increasingly, we see traditional surgical judgment replaced either by financial considerations or plain ego on the part of the surgeon.

Furthermore, it is easy for a well-meaning surgeon to be deceived about a patient's pathologic motivation. Because patients with BDD may not be identified as such in initial consultation with the plastic surgeon, medical disputes about the surgical outcome depend entirely on what was said versus what was understood. For this reason accurate, detailed documentation is absolutely essential.

In the best of all possible worlds, the prospective patient would project from the mind onto a screen exactly the changes he or she conceives so the surgeon could decide whether he or she can translate that image into reality. Lamentably, we have not yet achieved such imaginary technology.

It is also conceivable that the physical deformity really is at the center of the patient's psychological fragility. There are many examples of beneficial change wrought through successful aesthetic corrective surgery. Nonetheless, statistically the odds for an unfavorable result and a claim are much greater when the comparison between the objective deformity and the distress it creates in the patient is out of proportion. The surgeon must assess for appropriate psychological balance in early interviews with the patient and to lean strongly away from surgery in a patient for whom there is doubt of such balance.

At a time of large-scale changes in health care delivery in the United States, certain socioeconomic factors also come into play. With the rising number of practitioners in many specialties, competitive pressures affect patient selection criteria. There is a trend toward substitution of economic considerations for surgical judgment. Because of recent constrictions on medical incomes, some practitioners seem to see elective aesthetic surgery as the last area of practice unencumbered by either insurance or governmental restrictions. This has attracted individuals with inadequate qualifications. Even within the ranks of board-certified plastic surgeons, the trend toward aggressive marketing of services and the need to "sell" surgery has further blurred patient selection criteria.

Concluding Thoughts

It is possible to reduce the likelihood of all these unpleasant experiences by application of simple principles: maintaining good communication and rapport with the patient through good times and bad; restricting your practice to those procedures with which you feel thoroughly comfortable; close and careful attention to documentation of your activities; and above all, the realization that a normal temperature and a valid credit card by themselves are very poor criteria for elective aesthetic surgery.

Clinical Caveats

The four most critical elements for successful plastic surgery are competence, appropriate patient selection criteria, documented disclosure, and true informed consent.

The surgeon should rely on the counsel of more experienced plastic surgeons or psychiatric colleagues when uncertainty exists in patient selection.

The plastic surgeon's exposure to professional liability is unique in that he or she is treating a well patient to make him or her better (not assuming the care of a sick or injured patient to make him or her well), and the patient judges the results of treatment according to subjective standards, often colored by the patient's self-image.

By weighing how he says something more heavily than what he says, a surgeon can reduce the patient's image of him as omnipotent to that of a more realistic and imperfect human being, who is facing, and thus sharing, the same uncertainty.

The ability to communicate clearly is probably the most outstanding characteristic of the claims-free surgeon; communication is the sine qua non of building a physician-patient relationship.

Anatomic unsuitability and psychological inadequacy make a patient a poor candidate for elective aesthetic surgery. A strongly motivated patient will tend to have less pain, a better postoperative course, and a significantly higher index of satisfaction.

PART III

NONSURGICAL COSMETIC TREATMENTS

CHAPTER 9

Clinical Decision-Making for Nonsurgical Cosmetic Treatments

FOAD NAHAI

In today's fast-paced life, our patients want to look their best yet may not have the time to recover from open surgical procedures. Ubiquitous media and advertising claims promise that they can undergo facial rejuvenation during their lunch hour, or even invasive surgical procedures from which they can recover in only 48 hours. With the emphasis on a youthful facial appearance and an appealing, slim figure, much younger patients are consulting us about facial rejuvenation and body contouring.

We can choose from an array of nonsurgical treatments that for some patients come close to fulfilling the requirement of minimal treatment time with almost immediate recovery. We refer to these procedures as *cosmetic treatments*. In fact, any procedure that can be offered without a skin incision falls into this category. We further divide these procedures into those which are truly noninvasive (no skin penetration) and those in which a needle or laser penetrates the skin. This is an important distinction, because in my opinion, truly noninvasive procedures such as facials, light peels, and microdermabrasion can be safely performed by a trained aesthetician even in a nonclinical setting. More-invasive procedures, such as injections of toxins and fillers, and invasive laser treatments should be performed in a clinical setting, such as a physician's office or outpatient center, rather than at a spa or beauty salon. Some patients may simply faint at the sight of a needle, and very rarely, there may be an immediate allergic reaction to the material; these eventualities are easily dealt with in a medical environment. Although injectable toxins are safe in the hands of trained nurses and physician assistants, a physician should evaluate the patient, make decisions concerning treatment, and be available on the premises when a nurse or physician assistant is injecting toxins or fillers.

These treatments may be the primary treatment or an adjunct to open surgical procedures. In general, they are the primary treatment for a younger patient with early facial aging and an adjunct for an older patient who has already undergone facial rejuvenation procedures.

These procedures are also "practice builders." The young patient who today is undergoing microdermabrasion, toxin treatments, and filler injections will be tomorrow's face-lift patient. Research has shown that patients who are satisfied with their cosmetic treatments are likely to return to the same surgeon for surgical procedures as the aging process continues. It is a rare aesthetic practice that does not offer the full range of cosmetic treatments.

Cosmetic Treatments

Noninvasive	Minimally Invasive	Moderately Invasive
Spa treatments	Light-based treatments	Injectables
Facials	Microdermabrasion	Ablative lasers
External ultrasonography	Fruit acid peels	Peels: TCA, croton oil
	Nonablative lasers	Dermabrasion
	Sclerotherapy	
	Transcutaneous skin tightening	

Options for cosmetic treatments are constantly increasing. New and improved fillers and new toxins are regularly being introduced. An array of nonsurgical transcutaneous skin-tightening devices is under development or in early trials. Lasers continue to evolve, with noninvasive lasers that now can produce noticeable skin tightening. This rapid growth and innovation will inevitably lead to significant improvements in the materials and devices available today, and some of the devices and injectables of today may well be obsolete tomorrow. The first filler that I had any experience with was bovine collagen; it has been at least 10 or more years since I last injected it. It is important that those of us who inject these materials and operate the devices or supervise their use be familiar with the associated physics, mode of action, safety limits, risks, and limitations.

Most of these treatments have proved safe and efficacious, yet we must guard against excessive claims and clearly explain the limitations. Obviously, microdermabrasion is not a substitute for laser ablation or dermabrasion in a patient who has deep facial rhytids. Transcutaneous skin tightening is not a substitute for a face lift. A common reason for patient dissatisfaction with these cosmetic treatments is that the effectiveness of the treatment falls well short of the patient's expectations. Although I refer to these treatments as practice builders, exaggerated claims of their effectiveness, such as marketing them as a substitute for a face lift, will backfire and lead to loss of the physician's credibility.

Choosing the Right Option: The Needle and the Knife

In the first edition of this book, this section was entitled “Choosing the Right Option: The Needle *or* the Knife.” It is no longer a question of needle or knife; these are not competing but complementary treatment methods. We now have enough experience with injectables to know which patients are best suited for them, whose best interests would be served by the knife, and in which patients we can delay a surgical procedure by offering injectables. Before choosing the appropriate nonsurgical or cosmetic option, the patient and surgeon should make the fundamental decision together concerning surgical or nonsurgical treatment or a combination of the two. I like to think of this as the option between the needle and the knife. Many patients have already made their decision before the initial consultation, regardless of the suitability of needle or knife. It’s not unusual for young people who are nowhere near ready for a face lift to come in to discuss a face lift, while individuals with advanced facial aging who are no longer candidates for cosmetic treatments frequently ask for nonsurgical treatments. To most of the younger patients I recommend skin care, light peels, toxin, and injectables, if needed, while strongly advising patients to wait for the appropriate time to undergo a surgical procedure. To an older patient who is a candidate for surgical rejuvenation but comes in to discuss cosmetic treatments, I recommend surgical treatment as the first choice and discuss cosmetic treatments as a less effective alternative and perhaps a better adjunct to a surgical procedure rather than the primary treatment.

The choice between cosmetic treatments and open surgical procedures should be an informed decision. The patient must clearly understand that the effects of most cosmetic treatments are temporary and repeat procedures will be required. *An exception is injection of autologous fat as a filler, which I consider a surgical procedure requiring anesthesia and an operating room.* There is also a limit to the degree of rejuvenation offered by cosmetic treatments, and the patient must fully understand that these treatments are not a substitute for surgical rejuvenation.

This 55-year-old woman was a candidate for a full face and neck lift, blepharoplasty, and resurfacing. She fully realized that this was her best option, but her lifestyle and professional commitments would not allow her to put aside the time required to recover from full facial aesthetic surgery. Instead, she opted for toxin injections to the forehead and glabellar area and Restylane injections for the nasolabial folds and perioral areas. Clearly, a face lift and resurfacing would have produced a much more dramatic rejuvenation; however, the patient is satisfied with this suboptimal but modest improvement, which fits into her lifestyle.

This middle-aged woman realized that her best treatment option was surgical but chose less-invasive procedures. She underwent autologous fat grafting to fill the nasolabial folds, erbium:YAG laser resurfacing of the perioral area and lower lids, and toxin injections to the forehead and glabella. Her brow asymmetry is less noticeable following toxin injections.

Face

Most women undergoing noninvasive facial cosmetic treatments are seeking improvement of facial rhytids. I evaluate their rhytids at rest and on animation, we grade the rhytids by severity, depth, and extent of the problem, then we make recommendations. In addition, some patients also want improvement of skin blemishes, texture, and color. More and more younger women are seeking preventive maintenance. For them we recommend skin care, including tretinoin, and a general antiaging and nutritional program. Once our aesthetician and I have evaluated the patient’s skin and rhytids, we then classify the patient according to the rhytids, whether present at rest or on animation, and the depth of the rhytids.

Classification of Rhytids

Grade I	No rhytids at rest or on animation
Grade II	Superficial rhytids on animation only
Grade III	Deep rhytids on animation only
Grade IV	Superficial rhytids at rest, deep on animation
Grade V	Deep rhytids at rest, deeper on animation

GRADE I: NO RHYTIDS AT REST OR ON ANIMATION Grade I patients require only preventive and maintenance skin care. I advise them that it is too early for any surgical or invasive procedures and that their best interests would be served by preventive measures, including tretinoin and glycolic acid peels, if needed, but most of all we discuss skin health: avoiding environmental toxins, such as smoking and second-hand smoke, and taking precautions about sun exposure. Patients are also advised on general antiaging measures, including diet, exercise, and the use of antioxidants. We encourage these patients to come in for biannual follow-up visits. Once their facial aging proceeds to the next grade, the treatment plan is adjusted accordingly. Patients should understand that these preventive measures will not eliminate the aging of their skin and at best will delay visible signs.

GRADE II: SUPERFICIAL RHYTIDS ONLY ON ANIMATION For each successive grade, I recommend most if not all of the treatments of the preceding grade plus specific treatments for the current grade. Toxin injection is without question my first choice for this grade. By eliminating muscle function, especially in the glabella, forehead, and crow’s-feet, the lines are eliminated and the brow shape and position are improved. I would not recommend toxin injections for perioral lines at this grade. Toxin injections combined with the treatments outlined for grade I complete the recommendations.

GRADE III: DEEP RHYTIDS ON ANIMATION In grade III patients, for the glabella, forehead, and crow's-feet, toxins again are my first choice and by far the most effective treatment. However, toxin injections alone will not eliminate the rhytids but merely soften them in this grade. With these patients I discuss one of these additional options:

Deep peels such as trichloroacetic acid (TCA) (30% and higher)

Ablative lasers

Dermabrasion

Fillers of small molecular size, such as Restylane (Fine Lines)

For perioral lines and wrinkles, careful toxin injections may be considered in addition to the previously cited options.

I have found that most women will choose fillers rather than peels, lasers, or dermabrasion for their convenience, despite my caution that fillers are only a temporary solution. Most women are accustomed to the routine of regular beauty salon appointments for haircuts or coloring, so they don't necessarily find return visits to the cosmetic surgeon for touch-ups (which is required for toxin injections) to be objectionable. It further indicates that our patients would rather come back for repeat filler treatments than face the 10 days to 3 weeks of down time following ablative laser, peels, or dermabrasion.

GRADE IV: SUPERFICIAL RHYTIDS AT REST AND DEEP ON ANIMATION The recommendations for grade IV patients are essentially the same as those for grade III patients. However, any ablative procedures (lasers, peels, dermabrasion) will have to penetrate the skin more deeply. Not only will a larger volume of filler be required, but also injections will have to be performed at a deeper level.

GRADE V: DEEP RHYTIDS AT REST AND DEEPER ON ANIMATION Grade V patients are the best candidates for perioral administration of toxins, but as in grades III and IV, toxins alone is not sufficient. At this grade I may recommend a brow lift and a face lift if the rhytids extend beyond the perioral and periorbital areas, especially if severe rhytids are associated with loss of skin elasticity and the shifting of subcutaneous components. I also warn grade V patients that they may require retreatment of ablative laser therapy, dermabrasion, and peels within 6 months to 1 year of the initial treatment.

TREATMENT OPTIONS FOR RHYTIDS

Nasolabial Folds and Marionette Grooves

A number of patients consider deep nasolabial folds to be a sign of aging and seek consultation for improvement of their folds and grooves only. They feel that deep, overhanging folds make them appear to be frowning, angry, or unhappy. Although most of these patients would be best served through a combination of rhytidectomy and local treatments to improve on the folds, they often opt for local treatments only.

Unlike facial rhytids, which reflect the insertion of the muscles of facial expression into the skin, nasolabial folds and marionette grooves reflect not only muscle insertion and muscle pull but also adhesions of the dermis to the fascial layers of the face. Established nasolabial folds and marionette grooves are resistant to superficial and even deep ablative skin procedures. However, muscular manipulation with toxins and superficial and deep injections of filler materials can be very effective in ameliorating these folds. The deeper the fold, the deeper the level of injection and the more viscous the material. In addition to dermal and subdermal injections, filler materials may also be placed within the subcutaneous tissues. Many surgical options are also available, including various rhytidectomy procedures, as well as local excisions. Recommendations are made based on the grading of the folds.

Classification of Nasolabial Folds and Marionette Grooves

Grade I	Visible folds on animation
Grade II	Visible folds at rest
Grade III	Visible folds at rest and deepening of folds on animation
Grade IV	Deep folds at rest and deeper on animation
Grade V	Overhanging folds

GRADE I: VISIBLE FOLDS ON ANIMATION The first line of treatment for these patients is the use of filler material, injected superficially in the dermis. The choices include Restylane (especially Restylane Fine Lines), Juvéderm Ultra, and porcine collagen. Semipermanent fillers such as Radiesse are best avoided in the superficial plane.

GRADE II: VISIBLE FOLDS AT REST For grade II patients, treatment is similar to that for grade I patients, with injections in the superficial and deep levels. At this grade, patients may also be candidates for toxin injections.

GRADE III: VISIBLE FOLDS AT REST AND DEEPENING OF FOLDS ON ANIMATION

Grade III patients will require deep injection of filler material. The best filler in this area is autologous fat. Recommended fillers include, in order of preference, autologous fat, Restylane, Radiesse, and Juvéderm Ultra Plus.

In addition to filler materials, toxins are effective in treating patients of this grade. Toxin injections of the depressor anguli oris for the marionette grooves and the levator labii superioris and the levator labii superioris alaeque nasi for the nasolabial folds.

Although autologous fat is the best filler at this grade, most patients opt for the other fillers rather than go through the more extensive procedure and recovery associated with structural fat grafting. They opt for a less permanent result in favor of expediency.

GRADE IV: DEEP FOLDS AT REST AND DEEPER ON ANIMATION The recommendations are essentially the same for grade IV as for grade III, plus the option of surgical intervention: specifically, a midface lift in addition to autologous fat injection.

GRADE V: OVERHANGING FOLDS The recommendations of filler injections and toxin remain the same for this grade. As far as surgical interventions, I add the option of direct excision as an alternative to a midface lift. Should the patient choose to undergo a midface lift, the direct placement of autologous dermis fat graft or SMAS fat graft is an alternative to autologous fat injections. Most individuals in grades IV and V are more suitable candidates for rhytidectomy procedures, with injectable fillers as an adjunct.

TREATMENT OPTIONS FOR NASOLABIAL FOLDS AND MARIONETTE GROOVES

Periorbital Region

Although toxins are established as the treatment of choice for crow's-feet and periorbital wrinkling, fillers are rapidly gaining in popularity for rejuvenation of the periorbital area. The nonanimal synthetic hyaluronic acids (NASHAs) have an established role in the treatment of tear troughs and are being popularized for additional volume to the upper lid and brow. Some physicians think that fillers and fat are the preferred treatment for volume restoration in the periorbital area, obviating the need for extensive and complex surgical procedures. Care should be exercised when injecting fillers into the tear-trough area. The tissues are thin, and superficial injection may lead to the bluish discoloration referred to as the *Tyndall effect*.

Neck

Light- and medium-depth peels as well as judicious laser resurfacing play a role in rejuvenation of the neck, not only as a primary treatment but also as an adjunct after face lifts and neck lifts. Toxin also has a role in the temporary amelioration of platysma bands. In my practice I limit the treatment of the neck to light peels and toxin injection, because these are effective and relatively risk free. Ablative lasers and other more-invasive skin-rejuvenative procedures carry a great risk of scarring and unfavorable results in the neck.

Body

A number of patients are evaluated for skin changes on the exposed areas of the chest and upper extremity. These patients are candidates for skin rejuvenation. We offer them *body peels* (light glycolic acid peels), bleaching agents, and intense pulsed light (IPL) treatment of areas of dyschromia.

Skin-tightening devices have been advocated for the improvement of stretched, inelastic abdominal skin, and striae in particular. Improvements have been limited, and this treatment would not be an alternative to skin excision.

Hands

Injection of autologous fat into the dorsum of the aging hand is now an established and effective treatment. In addition, fillers have also been shown to rejuvenate the aging hand. Sclerotherapy of prominent dorsal hand veins is also beneficial.

Patient Example

This patient demonstrates lateral brow ptosis, glabellar and transverse forehead lines at rest, periorbital aging with tear-trough deformity, and deepening of her nasolabial folds, marionette grooves, and early jowls. She has had toxin injections to the crow's-feet, glabella and forehead, and the depressor anguli oris and mentalis muscles. NASHA fillers were injected into the lower eyelids, nasolabial folds, marionette grooves, and along the jawline to minimize the jowls. Her only surgical procedure was excision of the mole on the right side of her chin. The effectiveness of this nonsurgical treatment is clearly demonstrated on the split view.

Concluding Thoughts

Noninvasive treatments for facial rejuvenation have become the most popular of all cosmetic procedures, with toxins being by far the most common cosmetic treatment worldwide. Our choice of fillers has expanded so that we can pick and choose the appropriate filler for a given area. The role of injectables has now gone beyond facial rejuvenation and will continue to expand. Injectables have proved safe, effective, and popular with surgeons and patients alike. The search continues for other modalities of treatment that have the same attributes. Cosmetic treatments are not a substitute for surgical facial rejuvenation but are relatively effective stopgap measures that will allow most patients to postpone full surgical rejuvenation until a face lift is really needed or the patient has time to go through the recovery of a face lift. For all cosmetic surgeons, this remains a growth area and an opportunity to attract tomorrow's face-lift patient today. It is also a way to offer patients a full range of options to better meet their needs.

CHAPTER 10

Skin Care and Dermatologic Treatments

INJA BOGDAN ALLEMANN, DAVID J. GOLDBERG

Skin care and dermatologic treatments comprise a range of measures that are applicable to every person, regardless of his or her skin type, age, or underlying problem.

The seven basic goals of skin care are:

- 1. Cleansing
- 2. Protecting
- 3. Moisturizing
- 4. Preventing skin aging
- 5. Slowing the effects of aging
- 6. Reversing the effects of aging
- 7. Treating specific problems

Cleansing is a simple but important aspect of skin care. The skin must be cleansed and protected from harmful exogenous factors and influences. Because the skin is the outermost organ in direct contact with as well as a barrier against the environment, it is also the area in which the aging processes are most clearly seen. Consequently, skin care should also focus on preventing and slowing, or ideally even reversing the visible aging processes of the skin. Finally, dermatologic skin care treatments should address specific skin problems, such as erythema, pruritus, and inflammation.

This chapter focuses on skin care for the healthy individual who seeks medical advice for cosmetic and aesthetic problems. In addition to basic skin care, it will discuss more specific skin care needs that physicians may encounter regularly when treating cosmetic patients.

It presents a logical approach to skin care with a specific focus on protection, prevention, and reversal of cutaneous aging. There are three basic categories to consider when defining a skin care regimen: primary prevention, secondary prevention, and tertiary measures.

Approach to Antiaging Skin Care	
Primary prevention	Measures undertaken before any signs of skin aging or aesthetically bothersome skin changes have developed
Secondary prevention	Measures undertaken when signs of skin aging, such as fine lines and pigment alterations, begin to develop and are visible
Tertiary measures	Measures undertaken to target already progressively aged skin, with clear wrinkles and folds, volume loss, pigment irregularities, or obvious aesthetically disturbing skin changes

Patient Profiles

Following are examples of typical candidates for each category of care.

PRIMARY PREVENTION This 26-year-old patient with no signs of skin aging is a candidate for primary prevention.

PRIMARY AND SECONDARY PREVENTION This 37-year-old patient has the beginning signs of skin aging, such as fine lines and slight pigment alterations. She is a candidate for primary and secondary prevention.

PRIMARY, SECONDARY, AND TERTIARY CARE This 46-year-old patient has clear signs of skin aging, with medium-depth wrinkles and folds and the beginnings of volume loss and pigment irregularities. She is a candidate for primary and secondary prevention as well as tertiary measures.

Patients’ dermatologic characteristics and their needs and concerns are the central factors directly influencing what treatments should be suggested. Scientific and evidence-based data provide a sound basis for skin care and therapeutic measures.

Although the division of treatments into three categories is somewhat arbitrary, such an approach helps to organize patient needs in a structured way. These approaches should not be regarded as exhaustive and exclusive; they leave room for personal interpretation. The table shows the approach we use.

Approach to Skin Care and Dermatologic Treatments		
Primary Prevention	Secondary Prevention	Tertiary Measures
UV protection	Topical retinoids	Topical retinoids
Smoking cessation	<i>Botulinum</i> toxin	<i>Botulinum</i> toxin
Weight reduction	Fillers	Chemical peels
Healthy nutrition	Antioxidants	Fillers
Regular sports activities	Antiinflammatory agents	IPL laser
Minimal stress	Depigmenting agents	Fractional resurfacing
Topical retinoids	Nutritional supplements	Hair transplantation
<i>Botulinum</i> toxin	Vitamins	Blepharoplasty
Antioxidants	Coenzyme Q10	Face lift
Nutritional supplements	Minoxidil	
	Finasterid	

IPL, Intense pulsed light; UV, ultraviolet.

As can be seen, many of the treatments are listed in more than one category. A good example of this is the treatment of dynamic rhytids with injections of *botulinum* toxin. *Botulinum* toxin ideally prevents the formation of dynamic wrinkles and should thus theoretically be used before wrinkles even appear—hence as a primary preventive measure. One could argue, however, that *botulinum* toxin treats already formed dynamic wrinkles and should thus be employed as a secondary measure. In our opinion, treatment with *botulinum* toxin belongs in all three categories.

Skin Aging

The visible aging process of the skin starts sometime between the twentieth and thirtieth year of life and progresses gradually. Consequently, while still young, individuals need to focus on preserving the youthful qualities of their skin. The older the patient, the more that skin care should focus on slowing down, preventing, or even reversing the skin's aging process. The aging process has some unique characteristics for the skin that differ from those seen in other body organs.

Intrinsic and Extrinsic Skin Aging

There are two distinct processes of skin aging: intrinsic and extrinsic; these must be differentiated. *Intrinsic aging* is the process determined by our genetic predisposition, by the naturally and constantly occurring oxidative metabolism within our cells, and by cellular senescence, characterized by telomere shortening. Consequently, intrinsic aging takes place on the entire skin, progresses chronologically with age, and can probably not be prevented or influenced. In contrast, *extrinsic aging* is driven by exogenous factors, primarily by exposure to ultraviolet (UV) light, but also by such factors as nicotine use, air pollution, stress, and microorganisms. Thus extrinsic aging is not universal but takes place on exposed areas, such as the face, neck, back of the hands, and forearms. Extrinsic aging progresses at an individual pace, depending on the patient's exposure to the various damaging factors, and is consequently preventable to some degree, or at least influenceable. Historically, intrinsic and extrinsic processes were regarded as separate entities. However, newer data show that they share common molecular mechanisms. The two occur in parallel and lead to cumulative changes to the structure of the skin, its function, and appearance.

Causes of Intrinsic and Extrinsic Skin Aging

Intrinsic Aging	Extrinsic Aging
Genetic predisposition	UV light
Oxidative metabolism	Nicotine
Cellular senescence	Air pollution
	Microorganisms

UV, Ultraviolet.

Features of Intrinsic and Extrinsic Skin Aging

Intrinsic Aging	Extrinsic Aging
Chronologic	Individual
Entire skin	Exposed skin
Most probably not influenceable	Influenceable
Physiologic	Pathologic

Oxidative Stress and Reactive Oxygen Species

Oxidative stress, which skin is exposed to on a constant basis, plays a pivotal role in intrinsic and extrinsic aging. Oxidative stress is delivered by the creation of *reactive oxygen species* (ROS), also known as *free radicals*. Free radicals are formed naturally through normal human mitochondrial oxidative metabolism as well as through exogenous factors, such as UV exposure, air pollution, smoking, radiation, alcohol, exercise, and inflammation. The free radical theory of aging, which was proposed by Harman in 1956, is currently one of the most widely accepted theories to explain the causes of aging.

Free radicals can damage vital structures, such as DNA, cytoskeletal elements, cellular proteins, and cellular membranes. Recent data further suggest that free radicals can induce various transcription factors, such as activator protein-1 (AP-1) and NF-kappaB, and increase the expression of matrix metalloproteinases (MMPs), in particular collagenase, which degrades skin collagen and plays a central role in the skin's aging process. Clinically, these processes lead to photoaging, wrinkling, inflammation, erythema, edema, preneoplastic lesions, and skin cancer. Fortunately, the body also has defense mechanisms against such free radicals, called *antioxidants* (superoxide dismutase, catalase, glutathione peroxidase, alpha-tocopherol, ascorbic acid, glutathione, and ubiquinone).

As part of the natural aging process, however, the body's endogenous defense mechanisms decrease while the production of ROS increases, resulting in an imbalance and an increased number of unchecked radicals. Furthermore, antioxidant defense mechanisms can be inhibited by UV and visible light, whereas UV light exposure is known to increase the formation of free radicals, which only further tips the balance. These data provide the scientific background for the use of antioxidants, which have recently become very popular. (These are discussed in further detail on pp. 286-287.)

Anatomy of the Skin

The skin is composed of three layers: epidermis, dermis, and subcutaneous tissue, each with its specific function and characteristics.

Epidermis

The epidermis is the outermost layer of the skin and thus is vulnerable to exogenous assault. It is composed of various layers: the deepest is the basal layer, followed by the spinous layer, the granular layer, and ultimately the outermost layer, the stratum corneum, with its desquamating cells. The *stratum corneum* is the skin barrier to the environment and thus is important in protecting the skin from exogenous influences. The stratum corneum is important from a cosmetic standpoint because it is responsible for the texture, smoothness, and glow of the skin, the moisture level of the underlying epidermis, and the skin's pigmentation. The main cells that compose the epidermis are the *keratinocytes*, also called *corneocytes*. As they mature, these cells migrate upward to become the various layers of the epidermis, until they are desquamated on top of the stratum corneum. This keratinization process or cell cycle of the keratinocytes takes approximately 26 to 42 days. Retinoids can accelerate this cell cycle, resulting in younger keratinocytes in the stratum corneum and a smoother skin appearance. In between the keratinocytes is an intercellular lipid bilayer. This entire structure can be thought of as “bricks” (keratinocytes) surrounded by “mortar” (lipids), yielding the “brick-and-mortar” structural organization of the epidermis. The lipids are composed of fatty acids, cholesterol, and ceramides that help reduce transepidermal water loss. A disrupted skin barrier leads to increased transepidermal water loss and dry skin with a rough surface.

Melanocytes with their melanosomes are also located in the epidermis. These determine a person's physiologic skin color (skin phototype defined by Fitzpatrick; see p. 271). The number of melanocytes is relatively constant from one person to another and from one skin color to another. Differences in skin color are thus determined by the number and size of the melanosomes produced and distributed by the melanocytes. Pigmentary disorders can lead to an increased number of melanocytes or melanosomes in the basal layer of the epidermis and the upper layers of the dermis.

Dermis

Below the epidermis lies the dermis, which is composed mainly of fibroblasts, fibrocytes, collagen, and elastin, which together are embedded in an extracellular matrix. The dermis also contains nerves, blood vessels, and a variety of skin appendages. The extracellular matrix is composed mainly of glycosaminoglycans, which can bind their weight in water 1000-fold. This matrix plays a key role in an individual's cosmetic appearance, since it is responsible for the elasticity, flexibility, and volume of the skin. With aging, the extracellular matrix and its thickness decrease, and the arrangement of various dermal components, especially the collagen and elastin, change dramatically. Collagen I is the most important and abundant collagen type in the dermis, followed by collagen type III.

With age, collagen becomes increasingly degraded, reducing the skin's durability and resilience. The amount of elastin decreases and aggregates in chunks, producing the typical histologic solar elastosis of intrinsically aged skin (see the section, *right*, on p. 269). The most cosmetically important glycosaminoglycan is hyaluronic acid. Hyaluronic acid's function is to bind water and help hold the moisturizing level of the skin. Glycosaminoglycans and hyaluronic acid show an age-related decline, leading to dry, saggy skin. Collagen, elastin, and glycosaminoglycans make up the three-dimensional structure of the dermis. As all of these decline and become rearranged, the clinical result is volume loss, reduced elasticity, and decreased suppleness of the skin. Unfortunately, most topical cosmetic treatments do not penetrate into the dermis; thus it is difficult for them to reverse these changes.

Subcutaneous Tissue

The subcutaneous tissue is located below the dermis and is composed of adipocytes, surrounded by fibrous tissue and blood vessels. The subcutaneous tissue's distribution throughout the body depends at least in part on sex and age; redistribution occurs as the individual ages.

Not only do the changes of intrinsic and extrinsic skin aging differ in terms of their cause, they also differ in clinical and histologic presentation.

Clinical Features of Intrinsically and Extrinsically Aged Skin

Intrinsically aged skin, seen on sun-protected areas of the body such as the back, buttocks, and abdomen, is dry, thin, and lax. It shows fine wrinkling and regular pigmentation. Extrinsically aged skin, which we can see on sun-exposed areas such as the face, neck, chest, the back of the hands, and forearms, is thickened, shows deep folds and wrinkles, and has irregular pigmentation.

Histologic Changes of Intrinsically and Extrinsically Aged Skin

Histologic section through intrinsically aged skin

Histologic section through extrinsically aged skin

Intrinsically aged skin shows atrophy and thinning of the epidermis, with flattening of the dermoepidermal junction. The dermis also becomes thinner and the amount of collagen fibers, elastin, and extracellular matrix are all reduced.

Extrinsically aged skin shows an increased thickness of epidermis and dermis as a result of cellular hyperproliferation, with qualitatively and quantitatively changed dermal matrix proteins. Impaired fibrous structure is seen, with accumulation of fragmented elastic fibers, mucin, and glycosaminoglycans, leading to the characteristic histologic findings of solar elastosis. Increased melanin production leads to clinically obvious hyperpigmentation.

Functions of the Skin

The skin has numerous functions:

- Barrier against the external environment
- Regulation of moisture
- Production of sweat
- Production of sebum
- Immune defense
- DNA repair
- Wound healing
- Thermoregulation
- Cell growth
- Vitamin D production
- Vascular reactivity

If any of these functions are impaired, as often is the case in aging skin, the problems listed below can occur.

Problems With Impaired Skin Function

- Impaired barrier function → dry skin, pruritus
- Impaired vascular reactivity → disturbed moisture control and thermoregulation → pruritus and abnormal temperature sensation
- Reduced sweat glands → reduced sweat production → disturbed thermoregulation
- Reduced sebaceous glands → reduced sebum production → dry skin
- Reduced number of Langerhans cells → reduced immune control → increased cutaneous dermatoses and infections
- Impaired DNA repair → benign → and malignant neoplasia
- Impaired wound healing → prolonged wound healing and ulceration
- Impaired vascular reactivity → increased telangiectasis

Skin Types

Before recommending any skin care regimen to a patient, the physician must know what skin type the patient has. When considering skin types, one must differentiate between the *skin phototype*, developed by Harvard dermatologist T.B. Fitzpatrick in 1975, and the “cosmetic” skin type. As the name implies, Fitzpatrick’s skin phototype scale classifies the skin by an individual’s response to exposure to UV radiation. Thus the phototype is determined by the individual’s constitutional skin color and ethnicity, the amount of melanin pigment in the skin, and the reaction to sun exposure.

Fitzpatrick’s Classification of Skin Types

Skin Type	Typical Features	Reaction to Sun Exposure
I	White	Always burns, never tans
II	White	Usually burns, tans with difficulty
III	White	Sometimes burns, tans average
IV	Moderate brown	Rarely burns, tans with ease
V	Dark brown	Very rarely burns, tans very easily
VI	Black	Does not burn, tans very easily

Assessment of a patient’s Fitzpatrick skin phototype is important and has implications for two issues of cosmetic relevance: the tendency to develop rhytids and the predisposition to develop postinflammatory hyperpigmentation or postinflammatory pigment alterations. Because individuals with Fitzpatrick skin types I to III have fewer melanin granules in their skin, they are naturally less protected from UV radiation. Hence they develop rhytids at an earlier age and to a greater extent. Fitzpatrick skin types IV to VI wrinkle less; however, in general, they show a higher tendency for postinflammatory pigment alterations (hyperpigmentation and hypopigmentation) after inflammatory dermatosis or minimally invasive procedures, such as peels and various laser treatments.

The cosmetic skin types patients refer to are the designations used by the majority of manufacturers in the cosmetic industry: normal, oily, dry, combination (oily in the T-zone), and sensitive.

Cosmetic Skin Types	
Normal	Balanced skin, neither oily nor dry. It has a translucent, soft, smooth texture and a healthy glow.
Oily	Skin that has an oily shine as a result of overactive sebaceous glands with excess oil production. Often associated with enlarged pores and an irregular, coarse skin surface. Tendency to develop comedones and acne (“blackheads” and “pimples”).
Dry	Skin that does not shine, is dull, and frequently flakes. Skin feels dry and tight, especially after washing.
Combination	Oily shine in the so-called T-zone (forehead, nose, chin) and dry skin in the surrounding skin. This is the most common skin type.
Sensitive	Skin that often shows redness, flakiness, and irritation; may itch, burn, or sting. Skin that frequently reacts to various factors, such as weather and topical products.

Obviously, the cutaneous problems and requirements that cosmetic patients can present with are far more complex than can be reflected within these five categories. We think the most comprehensive approach for categorizing cosmetic skin types was developed and published by Baumann in 2003 (the Baumann skin typing system). Its classification is based on four main skin parameters:

- 1. Oily versus dry
- 2. Sensitive versus resistant
- 3. Pigmented versus nonpigmented
- 4. Wrinkled versus tight (unwrinkled)

To assess one’s individual skin type, Baumann’s book contains a questionnaire with separate questions for each parameter, with a score assigned to each parameter. The various combinations yield 16 potential skin type permutations. The book also provides comprehensive product recommendations and useful tips for physicians as well as consumers.

Baumann’s Sixteen Potential Skin Type Permutations					
	Oily, Pigmented	Oily, Nonpigmented	Dry, Pigmented	Dry, Nonpigmented	
Sensitive	OSPW	OSNW	DSPW	DSNW	Wrinkled
Sensitive	OSPT	OSNT	DSPT	DSNT	Tight
Resistant	ORPW	ORNW	DRPW	DRNW	Wrinkled
Resistant	ORPT	ORNT	DRPT	DRNT	Tight

D, Dry; O, oily; P, pigmented; R, resistant; S, sensitive; T, tight; W, wrinkled.

In discussing pigmented and nonpigmented skin, Baumann does not refer to light or dark skin types, but to an individual's tendency to develop pigmentary disorders, such as ephelides, lentigines, melasma, and postinflammatory hyperpigmentation. Unfortunately for the wrinkled versus tight skin types, most light-skinned people older than 30 years of age will fall into the "W" (wrinkled) category. These patients should use antiaging treatments such as retinoids, sunscreens, and antioxidants.

Baumann differentiates four types of "S" (sensitive) skin:

- S1: Patients prone to acne, with frequent breakouts, comedones, and predominantly oily skin
- S2: Patients prone to developing rosacea who complain of redness and broken vessels
- S3: Patients who frequently feel a stinging or burning sensation of the skin
- S4: Patients who tend to develop contact or irritant dermatitis.

The skin care regimen for individuals in this category, depending on the type of sensitivity, has to be adapted accordingly. The one quality that all of those with "S" skin types share is inflammation. In these patients, the inclusion of antiinflammatory agents into the various skin care products is crucial for a successful therapy and a satisfied patient.

Within the categories described, the basic concepts of skin care—cleansing, protecting, and preventing aging—apply to every patient seen by a physician, regardless of age, skin type, or underlying problems. The overall approach is simply to moisturize, slow down or even reverse aging, and treat specific problems. Two factors do need to be tailored to the patient's specific skin type: the kind of formulation used, and the active ingredients in the product.

From a professional treatment perspective, it makes sense to differentiate among more than the five basic skin types and to consider the aging status of the skin, potential pigmentary problems, and specific aspects of skin sensitivity. From a practical perspective, the treating physician should be aware of the special needs of oily or dry skin, aged skin, skin with pigmentary alterations, and skin with a tendency to sensitivity and inflammation. With knowledge of those features, the physician can formulate a personalized, comprehensive skin care regimen for each patient.

One consideration for sensitive skin applies to any treatment: when recommending or prescribing new products to a patient with sensitive skin, especially one who has a tendency to develop contact dermatitis, the physician should instruct the patient to test the new product for its allergenicity potential by applying it in the cubital area two times a day for 5 consecutive days. If by day 5 the patient does not develop contact dermatitis, the product should be safe for use on the face.

Evidence-Based Skin Care Musts: Retinoids and Sunscreens

As physicians it is our ultimate goal to recommend evidence-based and scientifically supported treatments. Unfortunately, when it comes to skin care and cosmetic products, this is a difficult task. There are only two treatments or substances whose use and biologic effects are backed by good scientific data: retinoids and sunscreens.

The sine qua non of any skin care regimen is the daily use of a sunscreen. In addition, as soon as the aging process starts and becomes a concern, daily application of a topical retinoid is advised. The use of topical antioxidants is also recommended, although currently there is less evidence of its efficacy from well-designed clinical trials than the other two products.

Cosmeceuticals

The cosmetic skin care market, especially products intended to reduce the effects of aging, is a multibillion dollar business. New products with new ingredients are constantly being developed. The sole purpose of “simple” cosmetics is to clean, smooth, and beautify the skin. Not much harm can be done with such products, and their purpose is well defined. However, this is not necessarily the case for another category of cosmetic products, called *cosmeceuticals*.

More and more biologically active ingredients are being included in cosmetic products that are not sold only for a beautifying purpose, but that claim truly biologic effects, such as photoprotection, antiwrinkling, antiaging, and skin tightening. These products all fall into the category of cosmeceuticals.

The term cosmeceuticals was first introduced by dermatologist Albert Kligman two decades ago. Today cosmeceuticals represent the fastest-growing segment of the skin care market. Cosmeceuticals constitute an intermediate between cosmetics and drugs (hence *cosme* from cosmetics and *ceuticals* from pharmaceuticals). In contrast to regulated drugs, these products are not sold for therapeutic purposes, but rather for cosmetic reasons. Thus cosmeceuticals are not regulated by the U.S. Food and Drug Administration (FDA) and consequently are not required to undergo the same rigorous premarket testing as do drugs. Unfortunately, this has led to a situation in which most cosmeceuticals manufacturers can claim various biologic effects for their products. Most cosmeceuticals lack large-scale, randomized, blinded, controlled clinical trials or long enough follow-ups to assess their actual biologic properties. Cosmeceutical manufacturers today assert that their products produce antioxidant, photoprotective, antiinflammatory, and collagen-stimulating effects. A vast array of cosmeceutical products claim antiaging and antiwrinkle activity.

Usually cosmeceuticals do show some effect in vitro. However, in vitro success does not prove in vivo efficacy. In vivo clinical trials of the final formulation are rare. An active compound might perform miraculously in vitro, or even in an in vivo animal model. However, when incorporated into the final formulation with preservatives and fragrances, there are many factors that might influence and change the active compound's biologic activity. Furthermore, for the active compound to penetrate through the stratum corneum, be absorbed into the skin, retain its stability, and stay at the specific structure long enough to exert its biologic effect requires complex processes that cannot be guaranteed by any in vitro data. Thus, even for an expert cosmetic physician, it is very difficult to assess a product's true biologic effects.

BASIC SKIN CARE

A Regimen for Any Skin Type and at Any Age

Cleansing

Cleansing the skin is the first step in every skin care regimen and should be routinely performed every morning and evening, regardless of an individual's skin type or age. The purpose of cleansing the skin is not only the removal of dirt, microorganisms, makeup, and other pollutants, but also the removal of desquamated cells from the skin surface. This allows skin to better absorb other topical therapies and aids in a constant rejuvenation process.

Using water alone for cleansing will remove roughly 65% of dirt and oil from the skin. However, water alone will not remove the oils from makeup and environmental pollutants.

To remove sebum and dirt, skin cleansers have to lower the surface tension of the skin. With this in mind, surface-active substances, the so-called *surfactants*, have to be added to skin care products. Surfactants represent the key active ingredient in cleansing formulations. They are also crucial components that influence a cleanser's degree of mildness or irritancy. The type of surfactant used varies by the type of cleansers, such as bars and liquids.

The main problem associated with the use of cleansers is a potential weakening of the stratum corneum by the surfactant's removal of the lipids required for the structure of the epidermis. When this occurs, the skin barrier is disrupted, leading to a disturbance in moisture level, a change in the skin's surface pH, and ultimately irritation to the skin.

Fortunately, cleansing technology has evolved greatly within the past two decades. At one time basic soap was used, which ultimately led to the introduction of synthetic detergent-based bars or liquids (the so-called *syndets*), which are non-soap-based surfactants. This has greatly helped to reduce the damaging effect of skin cleansers. Today most products recommended by aesthetic physicians are syndet cleansers.

Some cleansers can lead to immediate after-wash tightness, dryness, pruritus, and erythema. It is known that harsh surfactants, especially those contained in soap-based products, interact with proteins and lipids within the skin, which can lead to skin dryness, irritation, scaling, and roughness. Furthermore, a cleanser's pH plays

an integral role as to whether it will irritate the skin or damage the stratum corneum. Soap-based cleansers not only contain harsh anionic surfactants but also are alkaline and thus raise the pH of the skin, whereas syndets are mostly neutral or slightly acidic. Because of their pH, they remove less intracellular lipid. Various studies have shown a higher irritation potential for soap-based cleansers compared with cleansers with syndets.

Besides the main component of a cleanser (surfactants), these products contain various compounds, such as binders for stabilization of the formulation, sensory modifiers, fragrances, and preservatives. In addition, moisturizers (emollients and humectants) are now added to many cleansers; these help to maintain the hydration status and barrier function of the skin.

A cosmetic patient with an ideal skin care regimen will also apply some kind of topical retinoid to the skin. Although potentially helpful for collagen formation, retinoids may also weaken the skin barrier, making the skin prone to irritation. Many of the regularly performed cosmetic procedures, such as chemical peels and laser procedures, intentionally lead to an impaired stratum corneum. Hence the cleanser of choice for a cosmetic patient should be mild, nonirritating, fragrance free, noncomedogenic, and moisturizing so that it will not further exacerbate the already compromised skin barrier from other treatments.

Currently marketed cosmetic cleansing products for the face include soaps, superfatted soaps and beauty bars, dermatologic bars and liquid cleansers, lipid-free cleansers, syndet cleansers, and cleansing creams. Nonfoaming cleansers with no or a low level of surfactants are in general milder and less irritating than foaming cleansers, which contain surfactants. However, all nonfoaming cleansers are somewhat less efficient in cleansing. The lowest irritation potential will be provided by a cleanser that contains both nonionic/silicone-based surfactants and moisturizers.

The best currently available choice of cleanser for cosmetic patients is a liquid facial cleanser. These cleansers have an acidic pH, mostly contain moisturizers, and show a high “rinsibility.”

Patients with dry skin types should avoid foaming cleansers and use oil-based, moisturizing cleansers that are marketed as the following:

- Cleansing creams
- Cleansing milks
- Cleansing lotions
- Cleansing oils
- Hydrating cleansers

Patients with oily skin should avoid these cleansing types and use foaming or gel-based cleansers. Patients with aging skin that is not too sensitive or dry can intermittently use cleansers that contain glycolic acids. Although potentially irritating, such cleansers will increase desquamation and provide a mild antiaging effect.

Moisturizing

A 2004 study by Feldman and colleagues showed that after hydrocortisone (27.6%) and antiinfectives (23.4%), moisturizers (13.4%) are the third most commonly recommended over-the-counter topical product. Moisturizing the skin is a crucial component of every skin care regimen, not just for dry skin, which has been shown to have low levels of moisture. Moisturizers are helpful when there is a disturbed epidermal barrier with increased transepidermal water loss and thus a reduced water content in the epidermis. Skin can only be moisturized when the stratum corneum is intact, which allows the skin to trap the water in the dermis and viable layers of the epidermis. Too little water content in the skin will lead to dry skin with roughness, flaking, and irritation.

The goal of moisturizers is to increase the moisture level (that is, the water content in the stratum corneum), to provide a protective film, and to cover tiny disruptions in the skin while restoring the skin barrier function. Ultimately, this further reduces moisture evaporation from the skin, maintains the hydration level, and leads to both a smoother appearance and increased tactile properties of the skin. This can be achieved in various ways:

- By promoting water retention within the stratum corneum using humectants
- By minimizing water evaporation from the skin using occlusives
- By increasing the integrity of the skin barrier using occlusives

Emollients complement activity of the occlusives and aid in smoothing the surface of the skin. Most moisturizers contain all three components—humectants, occlusives, and emollients—in varying combinations.

Humectants

Humectants are water-soluble, hygroscopic materials with high water-absorption capabilities; they increase the ability of the stratum corneum to hold on to water by attracting and enhancing the water absorption from the dermis into the epidermis. In high-humidity conditions (atmospheric humidity greater than 80%), water can also be absorbed from the external environment into the stratum corneum. The reason moisturizers are formulated to combine humectants with occlusives is to prevent the enhanced water absorption from the dermis into the epidermis from being lost by increased transepidermal water loss.

By drawing water into the skin, humectants lead to a swelling of the stratum corneum, which smooths out fine lines and wrinkles. Many manufacturers of moisturizers use this phenomenon to claim antiwrinkle properties, although these products do not impart these effects long term.

The most effective humectant is glycerol (glycerin). Other commonly used humectants include propylene glycol, gelatin, natural moisturizing factor (NMF), urea, panthenol, sodium, sorbitol, and sodium hyaluronate. One of the newer and widely marketed humectants is hyaluronic acid. Many products containing hyaluronic acid claim its antiwrinkle activities, but as explained earlier, this effect is solely based on drawing water into the skin.

Occlusives

Occlusives are oily substances that reduce transepidermal water loss to the external environment by creating a hydrophobic barrier over the skin, supporting the lipid matrix between the keratinocytes, and thereby increasing the integrity of the skin barrier. Substances with occlusive effects include fatty acids (linoleic acid, lanolin), oils, waxes and wax esters (mineral oil, paraffin, petrolatum, silicone derivatives, squalene, beeswax), phospholipids, and sterols. Two of the best occlusives commonly used are mineral oil and petrolatum. Reduction in transepidermal water loss by petrolatum is 99%, and by mineral oil 50%. Oil-free occlusives include silicones such as dimethicone.

There is a subset of individuals with sensitive skin and a tendency for allergic reaction who develop contact sensitization to lanolin. Patients with known contact allergies should use moisturizers without lanolin. An example might be a moisturizer containing petrolatum, for which virtually no contact dermatitis has been reported.

Emollients

Emollients are mainly oils and lipids that help to hydrate the skin by filling the gaps between desquamating keratinocytes, leading to an increased cohesion of the corneocytic skin barrier. Emollients improve the appearance of the skin, increasing smoothness, softness, and flexibility, resulting in greater light refraction and more even-looking skin. There are various types of substances available with emollient properties. These include astringent emollients (such as dimethicone), dry emollients (isopropyl palmitate), fattening emollients (castor oil, jojoba oil, propylene glycol), and protective emollients (isopropyl isostearate). Various emollients, such as petrolatum, lanolin, and mineral oil, also possess humectant and occlusive properties.

The majority of moisturizers are either creams, which are water-in-oil emulsions, or lotions, which are oil-in-water emulsions. There are also more complex formulations available, such as serums and gels.

Creams are richer and tend to include heavier lipids. Typically creams contain mineral oil, petrolatum, lanolin, and water. Lotions are thinner, and in general, contain water, mineral oil, and propylene glycol.

Patients with dry skin need to apply a moisturizer at least twice a day, in the morning and in the evening. In dryer, less humid environments or in winter, a repeat application during the day might be needed. Ideally, creams are applied at night, whereas lotions can be applied during the day. Patients with markedly dry skin, or in dry climates, might need to apply cream in the morning as well. Moisturizers exert their most pronounced effect when they are applied on slightly dampened skin.

Patients with oily skin might not feel the need to apply moisturizer at all. However, no skin type is static; there are situations in which skin that is usually oily might tend to be drier and thus require a moisturizer. Ideally, patients with oily skin should apply the lighter lotions or even gels. Silicone derivatives in particular are targeted for those with oily skin.

The ideal moisturizer is noncomedogenic, nonirritant, fragrance free, hypoallergenic, and nonsensitizing. Patients with sensitive skin should choose this type of product.

Today newer moisturizers contain additional, mostly active ingredients, such as antioxidants, retinoids, and sun protectants. These moisturizers often claim to have additional effects, such as photoprotectant, antiaging, and sun protectant properties. Such products clearly belong in the category of cosmeceuticals. This antiaging technology is the fastest-growing segment of the facial moisturizer market.

Many moisturizers intended for use during the day contain a sun-protection factor (SPF). In general, the SPFs contained in daytime moisturizers are somewhat low (SPF 12, 15, or 20). Patients using these moisturizers should also apply sunscreen with an SPF 30 on top of the daily moisturizer. Moisturizers intended for nighttime and antiaging use will also often contain over-the-counter retinoids (retinol or retinaldehyde). These are excellent options to introduce the use of a topical retinoid to a patient's skin care regimen. (This is described in more detail on pp. 283 to 286.)

Protection

Photoprotection

Research over the past 40 years has made the association between sun exposure, photoaging of skin, and skin cancer indisputable. It has been clearly demonstrated that UV radiation causes skin aging. More important, UV light is now accepted as

the main etiologic factor in the development of cutaneous malignancy. In the United States, as reported by Ibrahim and Brown, 50% of all malignancies are attributable to skin cancer, and the increased rates of incidence of nonmelanoma skin cancer, as well as melanoma, are the fastest growing rates for any malignancy.

UV light can be divided into UVA (320 to 400 nm), UVB (280 to 320 nm), and UVC (190 to 280 nm). UVA and UVB rays are the clinically relevant radiation, because UVC rays are filtered by the ozone layer in the stratosphere. Acute effects of UV radiation on the skin include inflammation, erythema, sunburn, and pigmentation (tanning). Chronic irradiation with UVA and UVB leads to cutaneous immunosuppression, photoaging, and photocarcinogenesis. It seems that induction of inflammation and loss of skin elasticity can even be induced by suberythematous doses of UV radiation.

The clinical effects of sun exposure on photoaging can be easily visualized when comparing sun-protected body sites with sun-exposed ones. Photoaged skin shows remarkably more clinical changes than sun-protected, chronologically aged skin, such as sallowness, roughness, wrinkles, mottled pigmentation, telangiectasia, and various benign and malignant neoplasms.

Photoprotection is an essential prophylactic and therapeutic element to combat the deleterious cutaneous effects of UV radiation and to prevent and slow the signs of cutaneous aging. Photoprotection goes beyond skin care: in addition to sunscreens conferring photoprotection, sun-avoidance and protective clothing can add significantly to safeguarding the skin from damaging UV radiation.

Sunscreens

Data show that protection of the skin with sunscreen can reduce the development of skin cancer and inhibit photoaging. There have been tremendous developments in the sunscreen industry. In contrast to Europe, where sunscreens are regarded and treated as cosmetics, the FDA regards sunscreens as drugs and requires rigorous clinical trials before regulatory approval. This explains why certain sunscreen filters only enter the U.S. market after they have already been used in Europe for many years.

The SPF rating is used almost universally. However, SPF is primarily an indicator of protection from UVB rays, and the protection provided from the effects of UVA is somewhat difficult to estimate. In fact, commercially available sunscreens will provide reliable protection against UVB rays, whereas many of them will not be equally effective against UVA rays. SPF is defined as the UV dose (mainly UVB) required to develop a minimum erythema dose (MED) after the application of 2 mg/cm² of sunscreen. Hence an SPF 2 absorbs 50% of UV radiation and will allow a patient to stay in the sun double the time before developing erythema, as compared with the same patient who has not used the sunscreen.

With regard to UVA rating, the FDA recently proposed a new four-star grading system and a description (low, medium, high, and highest). The rating system includes in vitro and in vivo measurements and will be based on measuring the sunscreen's ability to reduce the penetration of UVA rays into the skin as well as to prevent tanning.

There are two different types of filters used in sunscreens: organic, also known as chemical filters, and inorganic, or physical filters/blockers.

Organic or Chemical Filters

Organic filters act by absorbing UV radiation and then emitting the absorbed energy as heat. They can be divided into UVA, UVB, and dual UVA/UVB or broadband filters. There are various filters with differing absorption spectra. To protect the skin over the entire UV spectrum, different filters may be combined in the same product. UVB filters include para-aminobenzoic acid (PABA) and derivatives, cinnamates and salicylates. UVA protection was revolutionized with the introduction of butyl methoxydibenzoylmethane (avobenzone); it was the first organic filter that provided some UVA protection. Recently, development has gone toward broadband UVA and UVB filters with the introduction of ecamsule (terephthalylidene dicamphor sulphonic acid, Mexoryl SX), dometrizole trisiloxane (Mexoryl XL), and bemotrizinol and bisotrizole (Tinosorb S and Tinosorb M). Chemical sunscreens can induce contact dermatitis in susceptible individuals. Such compounds include benzophenone, avobenzone, and PABA.

Inorganic or Physical Filters

Inorganic filters, also called *physical blockers*, are made of sizable particles that reflect and scatter UV and visible light. The two most widely used inorganic filters are zinc oxide (ZnO) and titanium dioxide (TiO₂). Another inorganic filter used is iron oxide. Depending on the particle size, such blockers not only reflect and scatter light, but absorb it as well.

The main problem with sunscreens containing inorganic filters is that they tend to leave a whitish discoloration and film on the skin, which is cosmetically disturbing. Newer formulations attempt to overcome this problem by the process of micronization; that is, producing smaller-sized particles, which results in less scattering of visible light and thus less opaque discoloration.

Currently there are no documented reports of sensitization reactions to physical filters. Thus inorganic sunscreens are the best choice for patients with sensitive skin who have a tendency to develop contact dermatitis.

Patients should be instructed to use sunscreen every day of the year, whether the sun is shining or not. Sunscreens should be applied in the morning 30 minutes before leaving the house. All sun-exposed areas should be treated. Patients should develop the habit of reapplying sunscreen at midday.

In our opinion, a daily sunscreen should ideally contain an SPF 30 and should protect from UVA radiation as well. When extended sun exposure is planned, such as on weekends and holidays, an SPF 50+ and high UVA protection may be considered and applied on all exposed areas of the body.

Patients with dry skin should use cream formulations to moisturize the skin. Patients with oily skin should use lotions or gels, since they are lighter than creams. Patients with sensitive skin will ideally use sunscreens with physical filters and avoid sunscreens with chemical filters, such as avobenzone, benzophenone, and PABA.

Patients with such pigmentary disorders as melasma, lentigines, and postinflammatory hyperpigmentation, which are known to worsen on sun exposure, should use an SPF 50+ and high UVA protection every day without exception.

Patients should be advised that a preexisting or acquired tan does not protect the skin from the sun and thus “pretanning” before going on vacations will only add to increased sun damage. Studies have shown that the photoprotection given by an acute suntan is only equivalent to a sunscreen SPF 2 to 3.

Because antioxidants are known to be photoprotective and lessen ROS-induced sun damage, newer sunscreens include antioxidants, such as vitamins C and E, green tea polyphenols, and resveratrol. However, such antioxidant sunscreens are less potent than physical filters in preventing sunburn.

A Regimen for the Prevention and Treatment of Skin Aging

Retinoids

Topical retinoids, together with sunscreens, are the fundamental agents used in topical cosmetic therapies. The term *retinoid* is used as a generic chemical term that encompasses the naturally occurring compounds with vitamin A activity, as well as the synthetic derivatives of retinol (retinoic acid). All retinoids exert their biologic effects by engaging and activating nuclear receptors.

Retinoids are classified into various generations, such as naturally occurring first-generation retinoids and synthetic or second- through fourth-generation retinoids.

Generations of Retinoids	
First-generation (nonaromatics)	Retinol Retinaldehyde Tretinoin Isotretinoin Alitretinoin
Second-generation (monoaromatics)	Etretinate Acitretin
Third-generation (polyaromatics)	Adapalene Tazarotene Arotinoid
Fourth-generation (pyranones)	Seletinoid G

The classic indication for the use of a retinoid is acne. The first anecdotal evidence supporting the positive effects of retinoids on photodamaged and photoaged skin was observed in a study performed by Kligman et al in 1986, when he treated female acne patients with topical tretinoin. The patients commented that their skin felt smoother and less wrinkled. Histologically, a replacement of the atrophic epidermis by hyperplasia, an elimination of dysplasia and atypia, an eradication of microscopic actinic keratoses, a uniform dispersion of melanin granules, and new collagen formation in the papillary dermis, as well as exfoliation of retained horn in the follicles were all noted. These data led to the conclusion that topical tretinoin is at least partly capable of reversing the structural damage of excessive UV exposure and may be useful in decelerating the photoaging process. Other studies followed, which ultimately resulted in FDA approval of tretinoin for the treatment of photo-damaged skin.

Subsequently various double-blind placebo-controlled trials have demonstrated that the topical application of retinoids can lead to improvement in global appearance, reduction of fine lines and coarse wrinkling, improvement of skin texture, and reduction of roughness, pigmentation, and sallowness. Most of the available studies documenting the effects of topical retinoids on photodamaged skin are on the effects of tretinoin, with significantly fewer data on the other retinoids.

Tretinoin

As previously discussed, the benchmark product for use in photodamaged skin—and currently the only FDA-approved topical retinoid for that specific indication—is tretinoin. Tretinoin is available in various concentrations from 0.01% to 0.25% and a variety of different formulations (creams and gels). The drawback of tretinoin is its irritation potential. If not instructed properly on the mode of application, patients can develop retinoid dermatitis with scaling, erythema, pruritus, and stinging.

Retinol and Retinaldehyde

Retinol and retinaldehyde are popular retinoids included in over-the-counter products. They have both been shown to be less irritating than tretinoin but still confer some degree of efficacy against photodamage.

Retinyl Palmitate and Retinyl Acetate

The esters retinyl palmitate and retinyl acetate can be found in various cosmeceuticals. However, they are not considered topically effective against photoaging.

Isotretinoin

Isotretinoin is a prescription retinoid marketed as a 0.05% gel or cream. It is less effective than tretinoin against the effects of photoaging, but seems to be less irritating.

Tazarotene

Tazarotene has been shown to reduce wrinkling and fine lines, skin roughness, and epidermal atrophy. It is a prescription retinoid available as a cream or gel at concentrations of 0.05% and 0.1%. Tazarotene has an irritation potential comparable to that of tretinoin.

Adapalene

Adapalene is approved for the treatment of acne and has been shown to be efficacious in the treatment of photoaging. Adapalene has been demonstrated to be less irritating than tretinoin and is a good choice of a prescription retinoid for patients with dry and sensitive skin. Adapalene is a prescription retinoid and available in cream and gel formulations of 0.1% and 0.3% concentration.

When patients are started on topical retinoids, it would seem reasonable to begin with an over-the-counter retinoid (retinaldehyde, retinol), because they are typically less irritating. This is especially important for patients with sensitive and dry skin. After 1 or 2 weeks with an over-the-counter agent, and assuming no skin irritation is noted, changing to a prescription retinoid would be a logical approach.

Although treatment with prescription retinoids should build up slowly, some patients, especially those with dry, sensitive skin, are at considerable risk of developing irritation and retinoid dermatitis. These symptoms seem to be related to the dose and type of retinoid used and typically occur about the second to fourth day after initiating application of a topical retinoid. There will even be a subset of patients who because of recurring irritation will not be able to apply a prescription retinoid every day. For these difficult patients, adapalene may be the preferred prescription retinoid, since it is much less irritating. On the other hand, patients with resistant and oily skin will be able to use tretinoin in its highest concentration right from the start, without developing any irritation.

Studies have shown that after 6 to 9 months, the frequency of topical retinoid application can be reduced to three times a week without compromising its efficacy. Topical retinoids can also be used on a continuous basis, because there seems to be no limit to the length of time a retinoid can be used.

Topical retinoids appear to be an effective long-term antiaging therapy. In general, the first clinical improvement, often seen after only 1 month of treatment, is an improved smoothness of the skin. After 2 to 4 months of treatment, a lightening of lentigines and mottled hyperpigmentation can be observed. Finally, coarse skin and fine lines are usually improved after 4 months of therapy.

Antioxidants

Although the human body possesses endogenous antioxidants, and certain vegetables and other foods are rich in antioxidants, it is thought that higher levels can be achieved by supplementation. Consequently, the use of antioxidants as oral supplements or topical formulations may lessen the harmful adverse effects induced by free radicals. It is believed that a combination of various antioxidants, orally and topically, may result in sustained antioxidant capacity as a result of synergistic actions of the combined antioxidants. The biologic effects of antioxidants are summarized in the box.

Biologic Effects of Antioxidants	
Antioxidative	Anticarcinogenic
Antiinflammatory	Depigmenting
Photoprotective	

Topical antioxidants are currently marketed for the prevention UV-induced skin damage and aging, as well as the treatment of rhytids and facial erythema. Based on current scientific data on antioxidants, the claim that antioxidants may prevent wrinkles may be justified. However, there are scant data on the use of topical antioxidants for the treatment of existing wrinkles. The box lists the current most popular antioxidants included in skin care formulations.

Agents With Antioxidant Activity

Coenzyme Q10	Grape seed extract	Resveratrol
Coffeeberry and <i>Coffea arabica</i>	Green tea	Rosemary
Ferulic acid	Idebenone	Silymarin
Feverfew	Lycopene	Turmeric/curcumin
Genistein	Mushrooms	Vitamin C
	Pomegranate	Vitamin E

Depigmenting Agents

Patients with photoaged skin often complain about hyperpigmented lesions, such as ephelides, lentigines, and melasma or PIH. A number of products are touted as “lightening creams.” None of them can magically erase such pigmentary lesions; all require months of use for visible improvement. Even with prescription lightening products, success is limited. To enhance efficacy it is best to combine the various available products and procedures that aid in lightening the skin. Optimal treatment requires the combined use of depigmenting agents, retinoids, sunscreens, and regular chemical peels and light- or laser-based procedures.

Topical depigmenting or skin-lightening agents can be divided according to their mechanism of action into tyrosinase inhibitors, melanosome-transfer inhibitors, melanocyte-cytotoxic agents, retinoids, and peeling agents.

Tyrosinase Inhibitors

Hydroquinone is an effective tyrosinase inhibitor that is available in over-the-counter products in a 2% concentration or less, or as prescription drug in a 3% to 4% concentration. Hydroquinone can be concentrated even higher in custom pharmacy formulations. However, higher concentrations are more irritating, leading to side effects such as skin redness. As with most skin-lightening agents, a prolonged application of 6 weeks or more is necessary before any improvement becomes noticeable. There

have been many concerns about the safety of hydroquinone, and in Europe it was banned in 2000 for general cosmetic purposes. Currently there is an ongoing debate in the United States as to whether the FDA will ban hydroquinone in over-the-counter formulations.

Other effective tyrosinase inhibitors found in cosmetic products or prescription drugs are aloesin and arbutin. Many flavonoids, found in various plants or flowers, display depigmenting effects, such as resveratrol, gentisic acid, ellagic acid, kojic acid, hydroxycoumarins, licorice extract, paper mulberry or mulberry extract, and emblicanin. Most of these products are included in cosmeceuticals.

Melanosome-Transfer Inhibitors

Niacinamide, or nicotinamide, is a popular depigmenting agent with additional antiinflammatory, antioxidant, and immunomodulant properties. Two proteins extracted from soymilk, namely soybean trypsin inhibitor and the Bowman-Birk inhibitor, have been shown to induce skin depigmentation. Because melanosome transfer inhibition is reversible, the safety profile of these products is excellent, with virtually no side effects.

Melanocyte-Cytotoxic Agents

Azelaic acid has been shown to be effective in the treatment postinflammatory pigment alteration.

Antioxidants

Many of the previously discussed antioxidants may lighten cutaneous hyperpigmentation in addition to their photoprotective, anticarcinogenic, and antiinflammatory activities. Examples of such antioxidants are vitamin C, vitamin E, pycnogenol, and silymarin.

Other Agents

Alpha-hydroxy acids and beta-hydroxy acid peels can be integrated into a skin care regimen aimed at the reduction of pigmentary lesions. As they are very safe, people with virtually any skin type can be candidates for alpha-hydroxy and beta-hydroxy acid peels.

Retinoids

The effects of retinoids on pigmentation have not yet been fully identified; they seem to involve various mechanisms. It appears that retinoids directly influence melanocytes and modulate melanogenesis. Clearly, by an acceleration of the cell turnover of epidermal keratinocytes, topical retinoids promote a decrease in melanosome transfer

to the keratinocytes and induce dispersion of keratinocyte pigment granules, leading to uniform distribution of melanin content in the epidermis. An increased epidermal turnover further reduces the cohesiveness of keratinocytes and induces their desquamation to an accelerated loss of melanin in the stratum corneum. Indirectly, the retinoid-induced changes in the stratum corneum facilitate the penetration of other depigmenting agents into the epidermis and increase their bioavailability and effects. The most popular depigmenting agents included in skin care formulations are listed in the box.

Agents With Depigmenting Activity

Aloesin	Linoleic acid/alpha-	Rucinol
Arbutin/deoxyarbutin	linolenic acid/oleic acid	Soy proteins (soybean trypsin inhibitor, Bowman-Birk inhibitor)
Azelaic acid	N-Acetylglucosamine	Vitamin C
Ellagic acid	Niacinamide	Vitamin E
Glabridin	Proanthocyanidins	
Green tea	(pine tree and grape seed extract)	
Kojic acid		

Antiinflammatory Agents

Patients who complain about sensitive skin with manifestations of erythema, flaking, tenderness, stinging and/or burning will profit from the inclusion of antiinflammatory agents into their skin care regimen. Most over-the-counter antiinflammatory agents are botanicals, some of which were used for centuries in ancient medicines. The box summarizes the most popular antiinflammatory agents included in cosmeceuticals.

Agents With Antiinflammatory Activity

Caffeine	Licochalcone	Resveratrol
Chamomile	Licorice extract	Silymarin
Cucumber extract	Mushrooms	Turmeric/curcumin
Feverfew	Oatmeal	Vitamin C
Green tea	<i>Polypodium leucotomos</i>	

Concluding Thoughts

Skin care is a multibillion dollar market, yet scientific data to support the biologic effects of various compounds and products are mostly lacking, or studies have not been designed in a satisfactory way. The only two scientifically well-researched topical cosmeceutical substances are retinoids and sunscreens. Sunscreens protect the skin from the detrimental influences of UV radiation. Sunscreens reduce photoaging and the development of skin cancer. Retinoids also prevent and partly reverse photoaging. In addition to the daily cleansing and moisturizing of the skin in accordance with one's personal needs, retinoids and sunscreens are the two most important substances to include in a daily antiaging skin care regimen. The use of antioxidants, depigmenting agents, and antiinflammatory agents is based on a sound rationale. However, most of these products provide only supporting in vitro data.

New ingredients enter the cosmetic market constantly. Unfortunately, clinical data are scarce or lacking for almost all of these products. Nevertheless, topical products are an important part of an effective skin care regimen.

Clinical Caveats

A patient's skin type and needs should be assessed first.

Skin care recommendations should be formulated according to the patient's skin type.

Every cosmetic patient should be educated on the importance of using sunscreen.

Patients need instruction on how to use topical retinoids to avoid irritation.

Light formulations such as lotions or gels should be used for patients with oily skin.

Richer formulations such as creams can be used for patients with dry skin.

Annotated Bibliography

Baumann L. The Baumann skin typing system. In Baumann L, ed. *Cosmetic Dermatology, Principles & Practice*, 2nd ed. New York: McGraw-Hill, 2009.

This is a comprehensive textbook on cosmetic dermatology with chapters on skin care, moisturizers, antioxidants, depigmenting agents, photoprotection, and much more.

Del Rosso JQ. Cosmeceutical moisturizers. In Draelos ZD, ed. *Procedures in Cosmetic Dermatology Series: Cosmeceuticals*. Philadelphia: Saunders, 2005.

This chapter explains moisturizers in detail, including their compounds and uses in cosmetic dermatology.

Draelos ZD, ed. *Procedures in Cosmetic Dermatology Series: Cosmeceuticals with DVD*. Philadelphia: Saunders, 2009.

A book dedicated to cosmeceuticals that explains in detail various compounds and their use in dermatology.

Lautenschlager S, Wulf HC, Pittelkow MR. Photoprotection. *Lancet* 370:528-537, 2007.

This review explains the latest and most important facts about photoprotection, various sunscreens, and the active compounds on the market.

Baumann L. *The Skin Type Solution*. New York: Bantam Dell, 2006.

This book explains the various skin types defined by Baumann and suggests various skin care regimens for each of them.

CHAPTER 11

Botulinum Toxin Injections for Facial Rejuvenation

ALAN MATARASSO, DAVID SHAFER

Since its initial FDA approval in 2002 for the temporary treatment of glabellar lines, Botox Cosmetic has transformed aesthetic medicine. Indeed, the word Botox has entered the vernacular, similar to such icons as Xerox for photocopies and Kleenex for tissues. ASAPS reported that Botox injections continue to outpace the top five plastic surgery procedures combined. With the FDA approval of Dysport (BoNTA-ABO, Medicis Aesthetics, Scottsdale, AZ) in 2009, a second *botulinum* toxin is now widely available commercially. A comprehensive understanding of the distinct differences and similarities between Botox Cosmetic (BoNTA-ONA, Allergan, Irvine, CA) and a non-type A *botulinum* toxin derivative such as Myobloc (BoNTB, Solstice Neurosciences, San Francisco, CA) is essential. The primary aesthetic use of *botulinum* toxin remains in the face and neck, although novel uses are expanding daily for aesthetic and nonaesthetic indications.

The aging face undergoes characteristic physiologic and structural changes that are reflected in the soft tissue layers and skeletal structures. Each region of the face—forehead, periorbital area, midface, lower face, mouth, and neck—ages in a distinct manner. Ultimately it is the contrast between what was and what is that motivates individuals to seek treatment to address this process. Numerous surgical and nonsurgical methods are available to rejuvenate the aging face. The goal of surgery is to address soft tissue laxity, loss of facial volume, and any tissue hypertrophy. Nonsurgical rejuvenation procedures are directed at the texture and quality of the skin and volume deficiencies in the dermis and underlying soft tissue. *Botulinum* toxin treatments address rhytids caused by hyperdynamic muscles of animation and, to some degree, help restore the imbalance created by age. Achieving a balance between dynamic rhytids from hyperactive muscles while maintaining natural facial animation is an important goal of *botulinum* toxin treatment. Naturally, there will be an overlap in the rejuvenation effects of various surgical and nonsurgical treatments. Rhytids caused by extrinsic aging (photodamage and heliodermatitis) and intrinsic chronologic aging and weight loss are common reasons that patients seek nonsurgical rejuvenation. Dermal photoaging, which is caused primarily by actinic damage to the skin, causes dermal thinning at a rate of approximately 6% per decade with thickened, degraded elastic fibers (elastosis), increased ground substance, and reduction in type I collagen. Concomitant changes occur in the epidermis and the subcutaneous adipose tissue. Muscular animation causes facial lines of aging to appear in most people and imprints individual patterns of facial expression. This accounts for the variations in appearance of individuals despite similar muscles of facial animation.

Nonsurgical treatment of facial aging can be described from various perspectives by the nature of the deformity (wrinkles, folds, and furrows), by the skin layer in which the defect occurs (epidermis or dermis), or by the technique used to address it (exfoliation, dermal and subcutaneous fillers, resurfacing, and chemodenervation). Because of the many causes of rhytids, various anatomic locations, individual patient preferences, and the effects of aging, optimal treatment often requires a multifaceted approach. Consequently, treatment objectives should be to prevent, restore, or reverse the cause of the problem. Ultimately the ideal treatment should be individual-

ized according to the causes and the patient's underlying anatomy, and this should be reconciled with the patient's goals and tolerance for the therapeutic options.

Nonsurgical Skin Rejuvenation for Facial Rhytids

Office-based nonsurgical skin rejuvenation for addressing facial aging is performed using one of these three methods, depending on the nature and location of concern:

1. *Botulinum toxin* is used for chemodenervation of the underlying muscles to prevent dynamic wrinkles in the overlying skin. In its absence, repetitive motion of the skin results in rhytids and dermal atrophy. Paralysis of the underlying muscle by *botulinum* toxin prevents continued movement and stress on the skin, improving the appearance of dynamic lines. Treatment can also improve static lines as dermal repair occurs. *Botulinum* toxin treatment also contributes, to some degree, to facial reshaping by decreasing muscle bulk or altering the dynamic balance between elevator and depressor muscles.
2. *Lasers, intense pulsed light (IPL), photorejuvenation, chemical peels, or dermabrasion* are used for softening static lines and the quality of the skin. These resurfacing techniques have their greatest benefit in leveling the epidermis and improving collagen in the dermis. Unlike *botulinum* toxin treatment, these resurfacing methods require varying lengths of recovery as the dermis and epidermis heal. Fractional techniques or subdermal techniques can effectively accelerate recovery time.
3. *Tissue fillers* are used to replace missing dermal components or subcutaneous volume. These injectable materials effectively augment areas of dermal atrophy by supporting the dermal matrix or by enhancing volume. Fillers show an immediate effect, and a plethora of products and applications exist.

Nonsurgical methods are often performed together, depending on the desired goal. These can also be used in conjunction with surgical procedures to complement, enhance, or address a condition that cannot be corrected through surgery. Nonsurgical procedures have broadened the scope of populations and problems that can benefit from them, but they should not be considered a replacement for surgical rejuvenation procedures. Self-applied prescription and cosmeceutical topical agents can also be beneficial and are designed to complement and supplement nonsurgical, physician-administered, in-office facial rejuvenation.

Of the three broad categories of treatments for nonsurgical facial rejuvenation, *Clostridium botulinum* toxin type A (BoNTA-ONA and BoNTA-ABO) injection is the method that most directly affects the underlying cause of the problem. In this chapter we will discuss the role of *botulinum* toxin in the nonsurgical management of facial aging, its advantages and disadvantages, and clinical applications for patients undergoing aesthetic surgery.

Dysport was approved by the FDA in 2009 for the treatment of glabellar lines and joins Botox Cosmetic as the second *botulinum* toxin type A approved in the United States for aesthetic treatment. The goals of and results from Dysport (BoNTA-ABO) treatments are similar to those of Botox Cosmetic (BoNTA-ONA). Nevertheless, it is essential that injectors understand the differences in unit dosing and dilution techniques between Botox Cosmetic and Dysport to achieve reproducible results with these two *botulinum* toxins. We will discuss general reconstitution of Botox Cosmetic and Dysport, dosing and storage guidelines, injection techniques, posttreatment protocols, and potential complications and how to avoid them.

On the horizon is an additional injectable neurotoxin (RT002) made by Revance Therapeutics (Newark, CA) and jointly licensed with Medicis. RT002 is an investigational injectable purified *botulinum* toxin type A that integrates Revance’s patented TransMTS peptide technology. The goal is that this injectable may enhance delivery of the toxin to the target site, which may enhance duration and safety of the drug. Also, Revance recently completed a different U.S. phase 2b trial with RT001, a topical *botulinum* toxin type A gel for the treatment of lateral canthal lines (crow’s-feet wrinkles).

Evolution of Technique

Botulinum toxin has a long history of use in clinical medicine and has been helpful for treating a range of conditions for which the principal therapeutic aim is to reduce undesired or excessive contraction of striated or smooth muscles. Scott is credited with the earliest successful use of *botulinum* toxin in ophthalmology. Thereafter it was used for the treatment of neuromuscular conditions, and indeed, it is considered by many clinicians to be a first-line therapy for focal dystonias. Novel uses are continually developed throughout the spectrum of medical specialties. The box identifies some of the myriad functional and aesthetic applications for *botulinum* toxin; other potential uses of *botulinum* toxin in medicine are yet to be determined.

Partial List of the Uses of Botulinum Toxin in Medical Therapy

Achalasia	Dental procedures	Hyperhidrosis	Spinal cord injury
Anal fissure	Esophageal stricture	Inner ear disorders	Strabismus
Back pain	Essential tremor	Masseteric muscle hypertrophy	Teeth grinding
Benign prostatic hypertrophy	Facial nerve disorders	Neck pain	Tourette’s syndrome
Blepharospasm	Facial spasms	Overactive bladder	Vasospastic disorders
Breast reconstruction and augmentation	Following Mohs micro-surgery repair	Parotid fistulas	Vocal cord disorders
Cerebral palsy	Gustatory sweating (Frey’s syndrome)	Poststroke limb spasticity	Temporomandibular joint dysfunction
Cervical dystonia	Headaches	Pressure ulcers	Wound healing
		Reduced appetite	

Nonaesthetic Uses for Botulinum Toxin Treatment

In 1989 Clark and Berris used *botulinum* toxin to temporarily restore forehead symmetry after a temporal branch motor nerve injury from a face lift. Carruthers and Carruthers, among others, spearheaded the transition in the use of Botox from ophthalmologic to dermatologic and cosmetic applications. They serendipitously observed the effacement of rhytids in patients treated with Botox who had blepharospasm associated with dystonia. Throughout the 1990s, numerous practitioners reported success with *botulinum* toxin for eradication of rhytids in an expanding number of facial regions. By the turn of this century, *botulinum* toxin injections had become the most frequently performed nonsurgical aesthetic procedure, and as the goals of treatment became more sophisticated, its use was expanded to include the entire face and neck and as a treatment for subtly altering facial shape. If the success of a new technology can be measured by its growth and broadening scope of application, then medical and aesthetic uses of *botulinum* toxin injections represent a phenomenon that is rarely seen more than once in a generation.

Chronology of Clostridium Botulinum Toxin in Clinical Medicine

Date	Event	Author
1897	<i>Clostridium botulinum</i> neurotoxin isolated	E. Ermengem
1920	Purification attempts	H. Sommer
1946	Crystallized type A purified	E.J. Schantz
1950	Therapy of hyperfunctional muscles	V. Brooks
1973	Pharmacologic weakening of extraocular muscles in monkeys	A.B. Scott
1979	Crystalline <i>botulinum</i> toxin A; batch 79-11	E.J. Schantz
1980	<i>Botulinum</i> toxin for treatment of strabismus in humans	A.B. Scott
1985	<i>Botulinum</i> A exotoxin used to treat blepharospasm	A.B. Scott
1985	<i>Botulinum</i> toxin used to treat spasmodic torticollis	J.K. Tsui
1989	FDA approves Botox Cosmetic for treatment of strabismus, benign essential blepharospasm, and hemifacial spasm	
1990	<i>Botulinum</i> toxin used to treat dystonias	J. Jankovic

2009	FDA approves BoNT-ABO (Dysport) for treatment of cervical dystonia and glabellar lines	

Role of Botulinum Toxin in Nonsurgical Rejuvenation

Botulinum type A is a powerful neurotoxic agent that specifically and physiologically denervates the mimetic muscles of facial expression, thereby eliminating their pull on the overlying skin. The resultant effect is temporary reduction in the appearance of dynamic lines of facial expression and, over time, improvement in static lines as well. *Botulinum* toxin therapy has also evolved from just a “wrinkle treatment” to a method of facial reshaping (elevating soft tissue), because muscular activity causes rhytids and soft tissue malposition. Drooping soft tissue can be manipulated by chemodenervation of muscles in the medial brow, lateral brow, corner of the mouth and jowl by altering the balance between agonist and antagonist muscles. Achieving an aesthetic balance in the muscles of facial expression while reducing the overlying dynamic rhytids is the goal of treatment. For example, the lateral brow has a propensity for ptosis from chronic animation, because of the lateral extent of the frontalis muscle, which ends at the temporal crest line, and the depressor effects of the lateral orbital orbicularis oculi muscle. Consequently, selective treatment of the medial frontalis muscle and corrugators (depressor) and denervation of the orbicularis oculi (accessory brow depressor) provide lateral brow elevation with a concomitant reduction in the appearance of crow’s-feet, resulting in a “chemical brow lift.” *Botulinum* toxin can also be used in conjunction with other methods of nonsurgical facial rejuvenation and/or surgery to achieve a variety of aesthetic goals.

There are eight types of serologically active paralytic *botulinum* toxins; type A (Botox Cosmetic, Dysport) and type B (Myobloc) are the two agents used in clinical practice. They exert their action by preventing the release of acetylcholine at the neuromuscular junction, thereby inhibiting repetitive muscle activity. This leads to the release of the superimposed cutaneous rhytid, which causes the formation of mimetic wrinkles or dynamic lines of facial expression and eventually contributing to dermal atrophy below the wrinkle. Units of biologic activity for different serotypes or formulations are not equivalent and cannot be easily converted to units of other *botulinum* toxins despite comparisons that have been suggested because of unresolved information. Although all *botulinum* toxins have comparable effects, no adequate studies are available for other serotypes such as *botulinum* toxin type B; thus valid conclusions about the efficacy, dosing, and suggested indications are currently incomplete. Currently treatment of glabellar frown lines (Botox Cosmetic 2002 and Dysport 2009) is the only FDA-approved cosmetic use of *botulinum* toxin, and even between these two type A *botulinum* toxins, *it cannot be overemphasized that despite similar treatment outcomes, the dilutions and doses are not equivalent.* In August 2004 Botox Cosmetic was approved for the treatment of hyperhidrosis. All other cosmetic uses for *botulinum* toxin A and B are considered off-label.

Many facial changes associated with the aging face can be attributed to underlying muscular activity, muscle hypertrophy, and patterns of facial expression for which *botulinum* toxin is an appropriate method of treatment. The early focus of *botulinum* toxin therapy was on hyperdynamic upper facial lines. Now its use has been extended to the midface and neck, often referred to as “extended uses.” In these locations, unlike the upper third of the face, the goal is often to weaken but not completely paralyze the muscle to avoid functional loss; for example, softening of vertical “lipstick bleed” lines by weakening the orbicularis oris or the levator labii superioris alaeque nasi to reduce the upper nasolabial crease. It is also now recognized that relaxation of or altering the balance between agonist and antagonist muscles of facial expression can lead to improvement in soft tissue ptosis and muscle hypertrophy.

An expanded use of *botulinum* toxin in aesthetic practices extends beyond the upper face. Nonsurgical reshaping of the lower face can be achieved through injection in the masseter muscles. This is most commonly done in Asian patients. In this indication, the goal is not paralysis, but rather temporary muscle atrophy. The depressor anguli oris or SMAS can also be treated to elevate the corner of the mouth or jowl.

Advantages and Disadvantages

In many respects *botulinum* toxin injection represents the ideal nonsurgical aesthetic procedure. It can be safely and rapidly administered, its effects are profound (essentially 100% successful), it is relatively painless, with no patient down time, it is technically straightforward to use, its effects are reversible within an acceptable period, and complications are uncommon and self-limiting. *Botulinum* toxin appears to be one of those rare therapeutic advances seen periodically over the course of a physician’s career that meets, fulfills, and even exceeds its potential and is destined to have a long-term, sustained impact on the practice of medicine, particularly cosmetic medicine.

Some characteristics of *botulinum* toxin might also be considered disadvantages, such as its reversibility or somewhat short length of therapeutic benefit. The toxin gradually “wears off” 2 to 4 months after treatment. Although some consider this acceptable, others think that its relatively brief duration is a disadvantage. The cost of the toxin is a drawback that can serve as an impetus for overdilution to obtain more volume. In addition, the prolonged consequences, if any, of acetylcholine blocked by *botulinum* toxin are unknown. Some concern has been raised in the media about migration of the neurotoxin into distant sites, including the brain. However, there have been no reported major adverse consequences from the injection of *botulinum* toxin for aesthetic indications using aesthetic dosages.

Indications and Contraindications

Certain patient characteristics and anatomic features help to define good, or conversely, less acceptable candidates for *botulinum* toxin injections. The ideal candidate should:

- Have a good understanding of the cause of his or her “disagreeable biologic condition” and the potential role of *botulinum* toxin in improving it

- Be aware that *botulinum* toxin’s mechanism of action is to address hyperkinetic muscles of facial expression, causing them to relax and therefore releasing the overlying wrinkle rather than filling it in or sanding it down

- Have relatively isolated defects that are not necessarily the result of overlapping conditions (dermal or subcutaneous fat atrophy, excess skin), in addition to the rhytid

- Understand the chronology of *botulinum* toxin’s onset of action and need for continued dosing to maintain the effects, although there is some “retraining” of muscles with repeated *botulinum* toxin use, resulting in intrinsic improvement

- Recognize the value of different surgical and nonsurgical treatments and their various timelines of effectiveness (for example, fillers, 6 months or more, versus *botulinum* toxin, 3 months)

Botulinum toxin should be used cautiously in patients with a propensity to bleed excessively (those with thrombocytopenia; a bleeding disorder such as hemophilia; or patients receiving anticoagulation therapy such as warfarin [Coumadin], clopidogrel [Plavix], or aspirin). Studies are lacking and there is an insufficient number of treated patients 65 years of age or older to make valid statements about the efficacy and safety of *botulinum* toxin in the elderly. Because of the greater frequency of comorbid medical conditions in this population, therapy should be initiated with low initial doses within the recommended dosage range. Despite any evidence of adverse effects, *botulinum* toxin should not be used in pregnant or lactating women or in women who are attempting to get pregnant. Currently the safety and efficacy of *botulinum* toxin have not been established in the pediatric and adolescent populations.

Finally, careful patient selection and counseling are important, because patients who are ill prepared for the paralytic effect and changes in facial morphology can experience untoward psychological adjustment following treatment. As with any aesthetic procedure, pretreatment photodocumentation is recommended to help resolve any issues raised by the patient following treatment.

Common Facial Aesthetic Applications of Botulinum Toxin

Upper third of the face (frontalis, corrugator supercilii/procerus, orbicularis oculi muscles)

Middle third of the face (levator labii superioris alaeque nasi, nasalis muscles)

Lower third of the face and neck (orbicularis oris, masseter, mentalis, depressor anguli oris, platysma muscles)

Following surgery (such as residual corrugator activity after excision), after liposuction of neck or submentoplasty with platysma muscle bowstringing or residual banding

Abnormal muscular hypertrophy (such as the temporalis or masseter muscles)

Combined with other rejuvenating procedures (injectables/fillers, in conjunction with resurfacing and soft tissue augmentation)

Contraindications to Botulinum Toxin Treatment

Patients with hypersensitivity to the ingredients (albumin, sodium chloride, *botulinum* toxin)

Patients with neuromuscular disease (myasthenia gravis, Easton-Lambert syndrome, motor neuron disease)*

Patients treated with *botulinum* toxin concurrent with other drugs that interfere with neuromuscular transmission—antibiotics (certain aminoglycosides, lincosamides, polymyxins), penicillamine, quinine, calcium channel blockers, neuromuscular-blocking agents (atracurium, succinylcholine), anticholinesterases, magnesium sulfate, and quinidine—all of which may increase the paralytic effect of the toxin (also potentially other serologic types of *botulinum*)*

Pregnant or lactating women

Patients receiving anticoagulation therapy/aspirin (a relative contraindication)

Patients with inappropriate anatomy (skin laxity, photodamage)

Patients with poor psychological adjustment or unrealistic expectations

Patients who are allergic to cow's milk protein (BoNTA-ABO: Dysport)

*These contraindications are based on interactions with drugs and intrinsic muscle disease, which could prolong the neuromuscular blockade effect of *botulinum* toxin.

Pertinent Anatomy

This illustration of relevant facial muscular anatomy shows the most common of the 44 facial muscles in which *botulinum* toxin is injected. The use of *botulinum* toxin for rhytids or to reshape or reposition structures requires an in-depth understanding of the function and location of the muscles of the face, their interactions (agonist versus antagonist), and the unique anatomic features of each region of the face. It is essential to precisely locate the muscles that are to be treated either clinically or by means of electromyography (EMG). We prefer to have the patient activate the muscle to be treated by a forced, exaggerated contractile motion intended to mimic the action of the muscle. The surface topography of that muscle will then be evident by the rhytid that is perpendicular to the body of the muscle (for instance, the orbicularis oculi) or enlargement of the muscle (for instance, the platysma). Anatomic landmarks, danger zones, or areas of altered anatomy from previous surgeries should be identified, along with the specific dosages appropriate to common muscle sites of *botulinum* toxin injection.

Botulinum Toxin: General Dosing Guidelines*

Area (corresponding rhytid)	Muscle	Botox Cosmetic (BoNTA-ONA) Units	Dysport (BoNTA-ABO) Units	Anatomic Landmarks or Danger Zones†
Forehead (horizontal forehead lines)	Frontalis	20-60	30-60	Inject in gridlike pattern; lateral portion of frontalis for 1-2 cm above brow injection will result in inability to raise eyebrow, or “brow ptosis.” To avoid this, inject above lowest fold produced by muscle action and M point. This will cause wrinkle to remain, maintaining brow elevation.
Glabellar complex (vertical and transverse glabellar lines)	Corrugator supercilii/procerus/orbicularis oculi (medial fibers), depressor supercilii	20-40	50-80	Inject in V pattern, staying medial to mid-pupillary line and avoiding injection below 0.5 cm from medial edge of eyebrow.
Bunny lines (side of nose)	Nasalis (transverse portion)	2.5 (per side)	6-15 (per side)	Inject just transverse portion of nasalis muscle.
Crow's-feet (lateral canthal rhytids)	Orbicularis oculi (lateral fibers)	5-15 (per side)	20-60 (per side)	Stay 1 fingerbreadth lateral to orbital rim and 3-4 injections in fan-shaped pattern. Avoid injection too far inferior (to zygomaticus major muscle) and possibly elevate cheek to demonstrate lines caused by zygomaticus muscle as opposed to pure orbicularis oculi muscle (squint).
Upper third of nasolabial fold	Levator labii superioris	2-5 (per side)	5-7	Confine injection to region of piriform aperture between nasolabial fold and nasal ala.
Upper lips (vertical rhytids)	Orbicularis oris	3-10	4-24	Inject small aliquots in lower third (for upper lip) and upper third (for lower lip) of orbicularis oris muscle.
Marionette groove	Depressor anguli oris	2-5 (per side)	20 (per side)	Identify muscle with patient actively pursing lips/chin 1 cm lateral and 1 cm inferior to angle of mouth.
Chin (cobblestoning)	Mentalis	5-10	10-20	Have patient project lower lip and chin upward. Inject at 3-5 sites intramuscularly into “cobblestoned” chin, just inferior to mental sulcus.
Neck (vertical bands)	Platysma	20-40 (per band)	40-80 (per band)	Isolate muscle cords with nondominant hand and inject entire length of body of muscle at 1-1.5 cm intervals from clavicle to its insertion in mandible. Inject subcutaneously for horizontal necklace lines. Avoid sternocleidomastoid muscle.
Masseter hypertrophy (infero-lateral facial fullness)	Masseter	25-30 (per side)	100-300 (per side)	Inject 5-6 points into body of muscle at mandibular angle. The goal is selective muscle atrophy, not paralysis.

*It cannot be stressed enough that Botox Cosmetic and Dysport do not have equivalent dosing on a unit-per-unit basis and that dosing guidelines for Dysport have not been firmly established.

†The surgeon must be aware of the effect that surgically altered anatomy has on muscle position. Dosage should be individualized according to muscle mass, patient response, sex, age, the desired effect, the time interval since the previous exposure, and the condition being treated.

Fundamentals

Pharmacology and Reconstitution

Botulinum neurotoxin type A (BoNTA-ONA: Botox Cosmetic and BoNTA-ABO: Dysport) is one of eight serologically distinct and species-specific toxins produced by the anaerobic bacterium *Clostridium botulinum*. It is a gram-positive, spore-forming, obligate anaerobe that is found naturally in the soil. It is produced by fermentation of strain *C. botulinum* type A grown in a culture medium.

The culture solution is purified and dissolved in sterile sodium chloride containing human albumin and is then sterile-filtered before filling and vacuum drying. It is commercially available as a sterile, lyophilized powder without preservatives. Each single vial of Botox Cosmetic contains 100 units (10% variation) of *botulinum* type A neurotoxin complex, 0.5 mg of human albumin, and 0.9 mg of sodium chloride. A 50-unit vial of Botox Cosmetic is also available.

Each vial of Dysport contains 300 units of *botulinum* type A complex, 125 μ g of human serum albumin, 2.5 mg of lactose, and trace amounts of cow's milk protein. A 500-unit vial of Dysport is also available for cervical dystonia. *It is important to note that Botox Cosmetic and Dysport are not equivalent on a unit-per-unit basis—100 units of Botox Cosmetic is not equivalent to 100 units of Dysport.* Each product is kept refrigerated at 2° to 8° C (35.6° to 46.4° F). At the time of use, it is reconstituted with 0.9% sodium chloride injection, resulting in a clear, colorless, odorless solution that the manufacturer recommends be used within 24 hours.

The rubber stopper can be removed from the vial before mixing to prevent foaming, which anecdotal reports state can potentially denature the toxin, and the saline solution is introduced by means of a 1 ml Luer-Lok syringe with a 22- or 25-gauge needle. The same needle is used to withdraw the reconstituted solution and is then replaced with a 1/2-inch 30- or 32-gauge needle, which is used for injection.

Mechanism of Action

Both BoNTA-ONA (Botox Cosmetic) and BoNTA-ABO (Dysport) are composed of *botulinum* toxin type A, each with a unique toxin/protein complex. The different complexes result in the differences in unit dosing between the two products. Once injected, the *botulinum* toxin core quickly dissociates from the complex and diffuses to its site of action. The toxin produces chemodenervation by preventing release of acetylcholine at the neuromuscular junction of the peripheral nervous system and at ganglionic nerve terminals of the autonomic nervous system within 6 to 36 hours of exposure to muscle with maximum effect up to 7 to 14 days. The neurotoxic effects of *botulinum* toxin occur in three phases:

1. Binding
2. Internalization
3. Neuromuscular blockade

Following these phases, a chemical denervation results, with associated clinically flaccid paralysis of the targeted muscle. At therapeutic doses the toxin induces paralysis limited to the injected muscle; however, the toxin has the potential to cause paralysis or weakness of adjacent muscles by diffusion and spread. The extent of muscular paralysis and atrophy correlates directly with the amount of toxin injected (concentration and volume of toxin solution). Diffusion results from toxin moving down its concentration gradient, which is affected by local receptor concentration. The spread depends on the solution volume and injection technique (physically pushing the toxin from the area of injection). There is an ongoing turnover (redevelopment) of neuromuscular junctions so that muscular function gradually returns after approximately 3 months, and axonal sprouting and reorientation of muscle fibers prevent permanent paralysis of muscles that are treated repeatedly.

Toxicity

Botulinum toxin is one of the most potent and neurospecific toxins known. It is estimated that in a 70 kg adult, the lethal dose of crystalline *botulinum* type A would be approximately 0.09 to 0.15 mg by the intravenous or intramuscular route, 0.7 to 0.9 mg by inhalation, and 70 mg if ingested orally. Considering the type available in the United States, it would be inaccurate to consider it as a potential bioterrorism agent, because each vial contains only about 0.3% of the estimated human lethal inhalation dose and 0.005% of the estimated lethal oral dose. The toxin does not penetrate intact skin, and person-to-person transmission does not occur.

The lethal dose of Botox Cosmetic is measured in units, with 1 unit being the lethal dose of toxin, causing death in 50% of a group of 18 to 20 g female Swiss Webster mice within 3 days of intraperitoneal injection. The median lethal dose (LD₅₀) has been estimated to be 2700 (2500 to 3000 units) in a 70 kg human, based on the median lethal dose of approximately 40 units/kg in primates. Species-specific sensitiv-

ity to the toxin precludes precise calculation of the human LD₅₀. The normal dose that does not produce toxicity is not known; however, single doses exceeding 500 units of BoNTA-ONA may produce acute symptoms and signs of botulism.

Dosages

The manufacturer's recommendations and initial FDA approval of Botox Cosmetic for treatment of the glabellar area were based on 2.5 ml (0.1 ml = 4 units) of unpreserved normal saline solution per 100 units of Botox Cosmetic for reconstitution. The maximum total recommended dose is 300 to 400 units at any one session and not more than 400 units over a 3-month period. The maximum dose of Dysport is 1000 units over a similar period. The dosage should be altered according to anatomic location, muscle mass, age, and sex of the patient, the patient's prior experience with *botulinum* toxin, the desired effect, the time interval since the previous exposure, and the condition being treated. Male patients may have a less profound and long-lasting result with *botulinum* toxin.

An acute awareness of the differences in dosing between Botox Cosmetic and Dysport is essential, since the "units" are not interchangeable. In general, Dysport is less active on a unit-per-unit comparison with Botox Cosmetic, which means that more units of Dysport are required to achieve similar clinical effects. With normalized clinical dosing, similar results can be achieved. Some studies, with electromyographic evidence, show that Dysport may achieve a clinic effect faster and maintain results longer than Botox Cosmetic. Continued clinical experience is required. Additionally, some practitioners have raised the concern of the smaller complex size of Dysport leading to a higher risk of diffusion. However, studies show that the toxin quickly dissociates from the complex under physiologic conditions once it is injected, precluding complex size from resulting in differences in diffusion. Perhaps because of this, some have claimed that Dysport produces a softer, more natural appearance. A distinction should be made between diffusion and spread. *Diffusion* is attributable to the total dose and receptor concentration because the toxin moves down its concentration gradient. *Spread*, on the other hand, is dependent on the volume injected and the injection technique; injecting a higher volume leads to increased physical distribution of the product as the fluid is pushed through the tissues from the point of injection. So diffusion or spread is a function of concentration gradient and physical force and is not attributable to the specific brand or formulation of toxin.

Dilution and Storage Considerations

There are two areas of frequent controversy regarding *botulinum* toxin that have yet to be determined: (1) the appropriate dilution of the toxin and (2) the method and length of storage of the reconstituted toxin. The manufacturer provides a table of 1 to 10 ml of dilution; however, physician preference remains the deciding factor. The glabella is the only area for which the FDA has approved injections and that is based on a dilution of 2.5 ml into a 100-unit vial of Botox Cosmetic or 2.5 ml and 1.5 ml

dilutions into a 300-unit vial of Dysport. Large dilutions with lower concentrations of toxins require larger volumes of injections to achieve the desired result, which can increase the potential for spread of the toxin to unwanted surrounding areas. For that reason we prefer a low volume and high concentration of *botulinum* toxin.

Type and Concentration of Botulinum Toxin

Type of Botulinum Toxin	Concentration (units/ml)
Dysport 300-unit vial	
1 ml	30/0.1
1.5 ml	20/0.1
2.5 ml	12/0.1
3 ml	10/0.1
Botox Cosmetic 100-unit vial	
2 ml	5/0.1
2.5 ml	4/0.1
4 ml	2.5/0.1
Botox Cosmetic 50-unit vial	
1 ml	5/0.1
2 ml	2.5/0.1

The length of viability of reconstituted toxin and the method of storage are also subject to controversy. We prefer using the toxin within 24 hours of reconstitution, during which time the unused toxin is kept refrigerated at 2° to 8° C. Some physicians refrigerate the toxin after reconstitution and have demonstrated a viable, albeit progressive, loss of drug efficacy over a 30-day period. If the toxin is stored, it should be reconstituted with bacteriostatic 0.9% sodium chloride preserved with benzyl alcohol to avoid bacterial contamination. Once the cap has been removed, the vial contents are no longer sterile.

Pretreatment Assessment

Physical Examination and Patient Education

A staff member interviews and evaluates the patient, who is given an informational packet to read before consultation with the physician. The medical history includes the patient's prior treatments with *botulinum* toxin, topical agents, or injectable fillers. The patient is asked to actively contract the intended muscle to be treated in front of a hand mirror, which helps to identify the muscle and serves as a tool for patient education. The patient is instructed to accentuate the specific facial lines to be treated by frowning (glabellar lines), squinting (lateral canthal lines), or elevating the brow (horizontal forehead lines). Patients never scrutinize their faces as much

before a procedure as they do after it has been completed; therefore it is important to identify and point out to patients the naturally occurring asymmetries that are present before treatment and to possibly obtain photographic documentation of baseline status. For example, there can be more aging on the left side of the face in general, and crow's-feet in particular, because of exposure to the elements while a person is seated on the driver's side of an automobile, and this side may need more toxin. Coexisting conditions in the field of treatment that will not be improved with injections (such as loose skin in the neck and static lines in the periocular region) should be identified and discussed with the patient. Planning for concurrent dermal filler or subsequent surgical treatment can be discussed. Unless one has prior experience that the patient has significant enough dermal atrophy to require correction with filler, we prefer to denervate the muscle with *botulinum* toxin and await the therapeutic benefit before determining the need for dermal filler supplementation.

Before treatment, the patient should be examined for preexisting ptosis. There are three types of "ptosis" that can be encountered before or subsequent to treatment:

1. *Drug-induced eyelid ptosis* results from diffusion of the toxin to the upper eyelid levator aponeurosis after injection of the corrugator muscle or crow's-feet. The cause and effect of this are largely unknown and speculative, since studies with direction injection of *botulinum* toxin into the levator muscle have occasionally failed to achieve ptosis. The treatment is medications that stimulate Müller's muscle, such as Naphcon A eyedrops 3 to 4 times daily or apraclonidine 0.5% after consulting with the patient's ophthalmologist. These drops provide approximately 1 to 2 mm of elevation and require continued use for sustained effect. Patients should have an eye examination before the agents are used; they should not be administered in patients with glaucoma.
2. *Preexisting eyelid ptosis* reflects the unmasking of preexisting upper lid ptosis that had been compensated for by frontalis muscle activity; treating the frontalis muscles with *botulinum* toxin unmasks this. The treatment is careful preoperative identification with administration of Müller's muscle agonist agents as indicated.
3. *True brow ptosis* is caused by loss of frontalis muscle activity, which is attributed to injection of the lower border of the lateral frontalis muscle 1 fingerbreadth below or above the brow. Patients may present complaining of heavy eyelids despite a lack of eyelid ptosis or inability to put on eye shadow. The correct treatment is to avoid this area and/or inject the antagonist depressor muscles, known as the *M point* of the orbicularis oculi. Before treatment, the efficacy against all forehead lines and the effect that has on brow position are discussed with the patient, including not treating the lower forehead lines to allow eyebrow movement. This is frequently the area of greatest patient concern. Moreover, surgical procedures to elevate and stabilize the lateral brow enable patients to have the lower rhytids treated with *botulinum* toxin. In addition, with elevation of the lateral brow there is less stimulus for the patient to contract the brow upward. Thus even without *botulinum* toxin the surgery alone improves the wrinkles.

Patients are instructed to cease using the following, if feasible, for 10 to 14 days before treatment to minimize ecchymosis: aspirin products, compounds containing vitamin E, nonsteroidal antiinflammatory agents, and dietary supplements that predispose them to bleeding or coagulation problems. As with any medical procedure, patients are asked to sign an informed consent form and HIPPA forms before treatment. Photographic documentation is beneficial. In addition, it is important to discuss the benefits and limitations of *botulinum* toxin treatment and review the alternatives or supplemental treatments that are valuable. Patients' questions are answered before treatment. We have an in-depth discussion with the patient about specific concerns, the cause of their "disagreeable biologic condition," and the therapeutic options available. We explain the specific role of *botulinum* toxin, the intended results, the length of its effectiveness, and potential complications. We are also careful to point out that unlike most filler materials, with which patients see an immediate result, the response to *botulinum* toxin is delayed (up to 14 days for final results).

Pretreatment Planning

Patient Preparation

Before treatment and the application of topical anesthesia, all areas of the face are cleansed of makeup and lipstick. Because patients want maximal benefit with minimal adverse effects or complications and a rapid recovery, every effort should be made to reduce patient discomfort. Therefore a topical analgesic is applied (lidocaine 4% [LMX4; Ferndale Laboratories, Ferndale, MI]) if requested; the patient is offered an anxiolytic agent if warranted; and cold compresses are applied to the intended sites to lessen discomfort. With the patient in an upright position, the product is injected into the region of the muscle according to its precise anatomic location. The dose of *botulinum* toxin varies, depending on the factors mentioned. Injecting a local anesthetic mimics the effect of the *botulinum* toxin action, which can serve as an educational tool for the patient.

Markings

For a typical office treatment, surgical markings are unnecessary, because in contrast to a surgical procedure, the patient is asked to repeatedly contract the muscle to identify sites for injection. The upright position does not distort the injection area. If the patient is having *botulinum* toxin injections intraoperatively, markings are made over the presumed body of the muscle, not necessarily over the deepest dermal rhytid.

Technique

11-1 Botox Cosmetic and Dysport: anatomy, supplies, techniques, and results

GENERALLY RECOMMENDED INJECTION SITES

Forehead	White dots	Frontalis muscle
	Black dots	Glabellar complex
Eyelid	Yellow dots	Orbicularis oculi muscle
	Red dots	M point of orbicularis oculi
Midface	Green dots	Upper nasolabial fold
Lip	White dots	Vertical lip lines
Chin	Blue dots	Mentalis muscle (cobblestoning)
Neck	Yellow dots	Platysma bands

With the patient in a seated position and after suitable preparation, each muscle of concern is identified and isolated. The intended muscle is isolated and stabilized or grasped with the nondominant hand. Injections are made into the region of the muscle according to its precise anatomic location.

Injection proceeds using proper injection techniques (injecting slowly perpendicular to a noncontracted muscle). Botox can be injected into various levels, such as the body of the muscle (corrugator, platysma), deep subcutaneous tissue overlying the muscle (frontalis), or superficially (orbicularis oculi). A serial puncture technique is preferred, rather than a bolus that is spread by massaging. Some physicians use EMG guidance to identify and isolate muscles, but this may have limited benefit in areas in which muscles are palpable, visible, and easily identified, such as those in the face. The purported advantage of EMG guidance is that it allows more accurate identification of the neural motor endplate, facilitating more precise injection and improv-

ing the effectiveness of lower doses of *botulinum* toxin. However, for general aesthetic indications this is rarely necessary. A postinjection protocol is then initiated.

The muscles are sequentially injected (intramuscularly [deep], or superficially [subcutaneously]). The solution is withdrawn in aliquots of 2.5 to 5 units of Botox Cosmetic or 5 to 10 units of Dysport (smaller increments for nasolabial and lip areas) at intervals of 0.5 to 1.5 cm apart, depending on the muscle and the intended result. With familiarity, the clinician performing the injections develops a sense of the necessary volume of injectate without observing the volume markings on the syringe. Some clinicians believe that *botulinum* toxin has a 3 cm target of spread (not unwanted diffusion from movement). Although this may be so, it may vary in different regions, and the perimeters of the zone of spread should not be relied on for chemodenervation; instead, sites beyond 1 to 1.5 cm require their own injection for reliable paralysis (wider zones of injection are feasible in the frontalis muscle). When completing each injection, the surgeon withdraws the hub of the syringe slightly by the thumb to prevent unnecessary spillage of the toxin. Alternatively, an insulin syringe can be used. These syringes do not have a Luer-Lok, so less toxin will be wasted. The disadvantages of an insulin-type syringe are that it is difficult to draw the solution into the syringe with the single-use needle, and the needle dulls quickly.

The fundamental principles for a successful outcome with *botulinum* toxin include the following:

- Proper reconstitution and storage of toxin
- Proper patient education, consent, and pretreatment preparation
- Proper muscle identification and isolation, and matching of the toxin dose to each individual patient's needs to achieve the intended result
- Proper injection technique
- Proper posttreatment protocol
- Frequent needle changes (the needle dulls with repeated use from multiple injections)

Combination Treatments

Botulinum toxin is commonly injected alone as monotherapy, although combination treatments during the same or subsequent sessions (fillers and resurfacing) can be used as necessary to treat the different layers of the skin and various conditions. For example, *botulinum* toxin can be injected into the frontalis muscle for dynamic forehead lines while avoiding the 1 to 2 cm above the brow so that muscle activity remains; substituting a filler in this area can help ameliorate the residual static lines. For deep glabellar lines (static and dynamic), a combination of *botulinum* toxin and

dermal filler may be necessary to achieve an optimal result. Numerous combinations are also possible. For example, *botulinum* toxin may be injected into the orbicularis oris muscle in conjunction with resurfacing (not simultaneously) or fillers to the lip and/or to the vertical lip lines. *Botulinum* toxin can also be used for crow's-feet, with laser resurfacing to the lower lid skin and fillers to the lower crow's-feet to avoid paralysis of the zygomaticus major muscle. When *botulinum* toxin is combined with a filler, it tends to prolong the longevity of the filler by decreasing the metabolism in the surrounding tissue. *Botulinum* toxin also has the potential to enhance the effects of laser resurfacing by improving collagen reorganization while the skin is paralyzed. In some areas, such as the upper third of the face, the physician can delay injecting filler material until the *botulinum* toxin is fully effective before resorting to the use of a filler. However, with nonsurgical rejuvenations, mixing and matching of products is common. One must keep in mind the differing timelines for longevity of the products or techniques used. Moreover, *botulinum* toxin can be used in conjunction with various depth peels and laser resurfacing.

Posttreatment Care

The most common adverse sequelae, ecchymosis and erythema, can be managed by applying gentle pressure with or without cold compresses to the treated site immediately after each site is injected. Patients are advised to actively contract the treated muscle in an attempt to (theoretically) enhance toxin uptake by causing more rapid internalization of the toxin (however, the usefulness of this technique has not been proved). Patients are instructed to resume normal activities immediately after their treatment session but are advised to remain upright and to avoid lifting, bending, or straining for 3 to 4 hours, particularly when the treated site is in the upper third of the face, to help prevent unwanted spread of the toxin. Essentially, the patient should hold his or her head upright as if balancing a book on it. Thereafter all activities are unrestricted. The consensus is that flying in an airplane and heat exposure do not have an adverse impact. The application of camouflaging agents or makeup is unrestricted.

Although adverse sequelae are self-limited, they do occur, and it is best to counsel the patient reassuringly. For the occasional patient who complains of headaches, nonaspirin products can be given. Vitamins and nutritional supplements can be administered as indicated, although whenever possible it is helpful to avoid these for 10 to 14 days before treatment to help prevent ecchymosis. Patients can return for a postinjection examination after 2 weeks and within the first 4 to 6 weeks if they suspect a therapeutic failure; beyond that it cannot be ascertained whether the muscle activity represents normal wearing off of the toxin or a therapeutic failure. Otherwise, patients are advised to return after a minimum of 3 months for additional treatments if they want to maintain the results.

Presumed therapeutic failures can often be attributed to the following:

1. A misunderstanding of the intended effect
2. The recruitment of surrounding muscle that was not intended to be affected
3. The patient's not being informed that residual static lines will not be improved by *botulinum* toxin treatments
4. A persistent rhytid resulting from dermal atrophy in the absence of underlying muscle activity

The effects of *botulinum* toxin injections can be observed as early as a few days later or up 14 days after treatment, depending on which muscle is treated and a variety of other factors. It is therefore advisable to wait 14 days, but within 4 to 6 weeks, and then examine a patient who believes he or she has had an inadequate response. If there is still residual muscle activity, additional *botulinum* toxin injections may be indicated. We usually do not advise "booster injections" within the 3 months after injection as the toxin is naturally wearing off.

Muscle activity begins to return gradually and waxes and wanes until approximately 3 to 4 months after injection, when full muscle mobility resumes. When proper precautions are taken to prevent complications of individual procedures, *botulinum* toxin can be administered before, during, or after surgical or resurfacing procedures without any adverse effects attributable to the combined modalities. However, consideration must be given to two situations related to *botulinum* toxin in a surgical patient:

1. If *botulinum* toxin is used intraoperatively or immediately postoperatively, the patient is potentially less likely to maintain the recommended inactivity to prevent spread.
2. In a postsurgical patient, the injector should be made aware of any anatomic (muscle) alterations related to the surgery.

Problems and Complications

Complications fall into three general categories: local, regional, and systemic. In addition, toxin "deactivation," immunologic responses, and therapeutic failure can be considered complications. Normal sequelae that are not true complications but that the patient may consider complications include needle marks, swelling, bruising, and mild erythema, or an earlier onset in one anatomic site versus another. Many of these normal effects that patients may consider abnormal are related to their preconceived expectations. The time of onset is an important indicator of a complication versus a normal sequela, because technical reactions are likely to be observed earlier than true complications.

Local, Regional, and Systemic Complications

There can be a fine line between what is considered normal sequelae and local complications. Local complications can include injection site pain, swelling, edema, erythema, rash bruising, ecchymosis, tenderness, headache, and short-term hypesthesias and can be related to the injection sites. S.L. Matarasso has summarized techniques to minimize these local complications.

The most notable and disfiguring regional complications occur when the toxins diffuse or migrate, spreading the neuromuscular blockade to unintended adjacent sites such as the zygomaticus major, which could be inadvertently injected during treatment of the orbicularis oculi, creating upper lip asymmetry or dysphagia or neck muscle weakness from platysma muscle injection. Other regional complications include loss of facial expression (a masklike countenance) from excessive paralysis, rendering the patient expressionless, or incomplete muscle paralysis with residual rhytids (similar to that which occurs in local complications).

Systemic reactions can include nausea, fatigue, severe generalized muscle weakness (only reported for patients in whom it was used in larger doses for noncosmetic purposes), malaise, flulike symptoms, distant rashes, respiratory arrest, and death. At therapeutic doses, *botulinum* toxin is not expected to be present in peripheral blood at measurable levels following intramuscular injection, nor does the amount of drug administered in a typical session appear to induce systemic effects. Distant neuromuscular effects have been documented but only from single-fiber EMG studies. The significance of these findings remains unclear. Isolated nervous system, respiratory, ocular, gastrointestinal (in patients with cervical dystonia—oral dryness, nausea, dysphagia, and dyspepsia), musculoskeletal, cardiovascular, dermatologic, and genitourinary complications have been reported with general (noncosmetic) uses of *botulinum* toxin and rarely if ever from the dosage range required for cosmetic usage. In fact, most of the literature on complications is from noncosmetic sources. It is suggested that practitioners report adverse events with Botox Cosmetic to the Medical Affairs Division of Allergan at 1-800-433-8871 or the FDA at 1-800-FDA-1088.

Immunologic Reactions

Immunologic complications include acute type I reactions and may be attributable to human serum albumin. This may result from the presence of circulating immunoglobulin G antibodies and is reported to occur in 3% to 5% of patients treated for cervical dystonia where large volumes of toxin are used. Since 1997, with a reduction in protein content to 20% of the original volume in the solution, there have been no reports of this complication. The development of antibodies seems to correlate with an increasing number of injections, frequency of treatment, and total cumulative dose of toxin. Since we began using *botulinum* toxin for aesthetic indications, we have encountered only two patients who were resistant to treatment, presum-

ably because of the neutralizing effect of antibodies. Limiting the total amount of toxin to less than 300 to 400 units of Botox Cosmetic per session and avoiding booster injections for a minimum of 3 months are recommended to prevent formation of these antibodies. Serum analysis can be performed to analyze for circulating antibodies, but is rarely indicated (*PacificBiolabs.com*). Injecting 15 units of Botox Cosmetic into one side of the frontalis muscle to observe for asymmetrical clinical effect can be used as a simple clinical test for resistance. *Botulinum* toxin type B (Myobloc/Neurobloc) may be considered as an alternative in patients with immunologic resistance to *botulinum* toxin type A as well as for other purposes. It is unlikely that another *botulinum* toxin type A (Dysport) would benefit a patient resistant to another *botulinum* toxin type A (Botox Cosmetic).

Therapeutic Failures

Therapeutic failures can range from no effect whatsoever after an injection to an unintended effect. A therapeutic failure can originate at various stages in the treatment process. Improper mixing (foaming), improper dilution or storage (wrong temperature), incorrect muscle identification, or failure to distinguish a static from a dynamic rhytid can also result in a therapeutic failure.

Botox “signs” are considered an unintended result caused by recruitment of untreated adjacent muscles, or an abnormal appearance resulting from loss of function in a treated muscle can be interpreted as a failure.

Outcomes

Results with *botulinum* toxin as a primary monotherapy or in conjunction with fillers, resurfacing, or surgery, when injected appropriately, are generally excellent. Indeed, unlike almost any other surgical or nonsurgical procedure used for facial rejuvenation, *botulinum* toxin can provide an “all or none” response (unless weakening of the muscle is the goal), making it 100% effective.

The most common causes of patient dissatisfaction with *botulinum* toxin treatment include the following:

- Inadequate understanding of the role of *botulinum* toxin in facial rejuvenation.
- Unpreparedness for the effects of *botulinum* toxin treatment, including temporary paralysis or altered balance of the muscles of facial expression.
- The psychological consequences of altered facial appearance.
- Suspected therapeutic failure that can be attributed to the recruitment of surrounding untreated muscles.
- Short-term local complications.

Rare general, systemic, or immunologic complications.

In the face, the most common concerns occur with treatment of the lateral third of the frontalis muscle over the brow, where injection will ameliorate rhytids but will also limit the patient's ability to elevate the eyebrows.

Results

This 57-year-old woman complained of forehead and glabellar wrinkling and cobblestoning of her chin. She underwent Botox Cosmetic injections to her frontalis (forehead), corrugator, procerus, and mentalis muscles. She is seen 4 weeks after treatment, with reduction in the appearance of her rhytids and cobblestoning in the mentalis area.

This 38-year-old woman presented with perioral rhytids and upper facial rhytids. She underwent *botulinum* toxin injections to her forehead, glabella, crow's-feet area, and her upper lip. She is seen 6 weeks after treatment. The results of her perioral treatment reveal a reduction in the vertical lip lines. Treatment here must be tempered with an awareness of the potential for loss of function and lip symmetry.

This 46-year-old woman presented with upper facial rhytids and cobblestoning of her chin and neck cords. She was treated with Botox Cosmetic injections to her frontalis muscle (forehead), corrugator muscle complex, orbicularis oculi muscles, and mentalis and platysma muscles. She is seen 1 month after treatment.

This 62-year-old woman presented with hypertrophic platysma cords and horizontal necklace lines. She was treated with *botulinum* toxin injections to her vertical platysma muscles and horizontal neck creases. She is seen 1 month after treatment. Improvement is evident in her hypertrophic right neck muscle cord, and the necklace lines have softened.

This 52-year-old woman presented with periocular and glabellar rhytids. She was treated with Botox Cosmetic injections to her corrugator-procerus muscle complex and the lateral orbicularis oculi muscle. She is seen following injection at the onset of the therapeutic benefits. The reshaping in the arch of her lateral brow is evident; this was produced by deactivating the depressor muscles in this area and allowing the elevator (frontalis) muscles to act unopposed.

Concluding Thoughts

Botulinum toxin injection is an aesthetic procedure that is essentially 100% effective. Its use has been enthusiastically embraced by physicians and patients, to the extent that the name of the first product approved for use in the United States, Botox, was rapidly incorporated into the popular vernacular. There are two types of type A toxins, Botox Cosmetic (BoNTA-ONA) and Dysport (BoNTA-ABO), that are FDA approved for the treatment of glabellar creases; all other indications are considered off-label.

The dilution and dosage of the two products are distinctly different. Practitioners must thoroughly understand the reconstitution, indications, technique, therapeutic benefits, and complications and their management for each of these agents. A type B alternative is also available for use (Myobloc), or for type A-resistant patients. Although the primary aesthetic use of *botulinum* toxin remains in the face and neck, additional applications are being developed for aesthetic and nonaesthetic indications.

Clinical Caveats

A new sterile needle and syringe should be used to enter the vial when reconstituting the drug and for withdrawal of each dose. The manufacturers consider each *botulinum* toxin vial to represent a single use.

If alcohol is used to cleanse the patient's skin or the rubber stopper on the vial, it should be allowed to dry before proceeding with the injection to avoid potential denaturation of the toxin.

The interval between full *botulinum* toxin treatment sessions should be at least 3 months.

The lowest effective dose of the drug should be administered.

Appropriate supportive care and therapy (epinephrine) should be available and initiated immediately if anaphylaxis or another severe allergic reaction occurs.

An anatomic data sheet or some other record is a helpful means of recording the date of injection, the sites of injection, the number of units used, any concomitant use of fillers, and the patient response (duration).

Dilution of the toxin with preserved (benzyl alcohol) 0.9% sodium chloride will help to relieve pain on injection. Injecting when the muscle is relaxed is also less painful. The toxin can also be reconstituted with lidocaine, which "previews" the effect of *botulinum* toxin, but also impedes the ability of the patient to contract the muscle after treatment, which may enhance toxin uptake.

Continued

Clinical Caveats—cont'd

Unlike fillers, the skin layer into which *botulinum* toxin is injected is not as critical, and results are less potentially operator dependent than with fillers.

Regularly repeated injections may render the muscle mass smaller, resulting in a faster onset of action and a longer response, or this effect may result in behavioral modifications (muscle “retraining”), causing the patient to avoid certain facial movements, thereby naturally improving the area.

Precise identification of muscular anatomy and needle placement is essential for a successful outcome. The injector must consider that any effect that *botulinum* toxin could have on anatomy may be altered if prior surgery has been performed.

Problems with dilution occur with greater volumes of diluent, such as more than 5 ml of saline/100 units of Botox Cosmetic, because spread becomes more dependent on excess volume of solution rather than on the drug itself.

When treating one of the agonist-antagonist muscle groups (frontalis and corrugator), for example, for facial reshaping, it may be advisable to counterbalance the opposing muscle with a small amount of toxin to avoid an imbalance when movement of an opposing muscle is lost. When counterbalancing muscles is not an issue (for example, in the orbicularis oris), one should consider the effect that paralysis of the treated muscle will have on function.

Facial anatomy (musculature) is similar from one patient to another; the degree of soft tissue malposition and rhytid formation will vary according to patterns of muscle usage (animation), resulting in different types of deformities that require different treatment approaches.

“Extended” areas of treatment such as the lower half of the face (nasolabial folds, upper lip lines, marionette grooves, jowls, chin dimpling, and the masseter) should be weakened rather than paralyzed to avoid a functional imbalance from loss of muscle activity. In these regions, adjunctive use or primary use of fillers is more common than *botulinum* toxin alone as monotherapy.

Softening the glabellar frown muscle complex that depresses the brow will help lessen the pull of the antagonist frontalis muscle and reflexly slightly improve transverse forehead lines.

Nonresponders who may require additional toxin should be evaluated to determine whether the response appears to be ineffective because the patient is recruiting surrounding muscles (the “shelf” that appears with smiling below a treated orbicularis oculi muscle from zygomaticus muscle activity) or a remaining rhytid that is caused by dermal atrophy, as opposed to an actual therapeutic failure.

At the end of the day, if there is not enough *botulinum* toxin left in the reconstituted vial to effectively treat a site and there is “one more patient” or site to be treated, a new bottle should be opened to provide adequate treatment, even if the bottle will contain leftover toxin and potentially wasted drug.

When there is leftover toxin, it may be refrigerated, preferably for not more than 24 hours. The next day it can be combined with a “fresh” solution of similar toxin.

Annotated Bibliography

American Hospital Formulary Service (AHFS). Botulinum toxin monograph. American Society of Health System Pharmacists (ASHP), 2003.

This is an extensively researched and referenced monograph detailing the biology, chemistry, toxicity, and extensive medical uses for botulinum toxins. It does not contain clinical examples but is an important, easily readable resource for in-depth information on botulinum toxin in all areas of medicine.

Matarasso A. Clinical usage of Botox. In Aesthetic Surgery Video Journal. New York: American Society for Aesthetic Plastic Surgery, TRT Productions, 1999.

This videotape provides live patient examples of Botox injections. Accompanying the treatment is a discussion by the surgeon about techniques and dosages. The video concludes with a discussion of complications and their management. It is a useful and practical guide.

CHAPTER 12

Soft Tissue Fillers in Aesthetic Facial Surgery

TREVOR M. BORN, LISA AIRAN,
DIMITRIOS MOTAKIS, FOAD NAHAI

Soft tissue fillers are an exciting tool for cosmetic surgeons striving to meet the growing patient demand for facial rejuvenation that requires minimal down time. For younger patients, these materials offer the potential for staving off the first visible signs of aging without the morbidity associated with more invasive surgical procedures. These materials are also appealing to individuals who want to look refreshed but do not want to take the time that a major lift would involve. Fillers also serve as an initial therapy for a young to middle-aged patient population with minimal to moderate signs of aging who regard fillers as the first step in the rejuvenation process. As these patients age, surgery, often combined with fillers and other surface treatments, becomes the next logical step in their quest to restore and maintain a youthful, refreshed appearance.

Today the number and variety of products available are impressive. Yet the ideal filler has not been found; neither have we agreed on the properties that would be appropriate for all fillers. For example, although permanence would clearly be a virtue, it could also be a negative if the filler used did not age appropriately as the patient’s soft tissues became ptotic and attenuated. Therefore reversibility is an important characteristic. Despite these reservations, there are certain basic qualities that we seek in the ideal filler material.

Ideal Filler Characteristics	
Nontoxic	Predictable (permanence, bulk, and behavior)
Biocompatible	Not discernible by touch/appearance
Long lasting (if not permanent)	Produces positive, natural, discernible change
Reversible	Involves minimal down time
Off the shelf	Offers multiple levels of placement (could be placed through dermis at subcutaneous, intramuscular, or periosteal levels)
Autologous	Performs well as a person ages
Easy to use	
Safe	

The worldwide search for the ideal soft tissue filler continues. It is exciting to see new products as they are introduced, but a balance is needed between embracing new devices and products and ensuring the safety of our patients. This chapter is intended to guide surgeons in making these judgments. Divided into two sections, it begins with an overview of currently available tissue fillers and provides information on their applications and approval status in the United States and internationally. The second section provides information on the clinical characteristics, applications, and techniques for sculpting with the more popular and commonly available fillers.

OVERVIEW OF CURRENTLY AVAILABLE TISSUE FILLERS

A variety of excellent products have been introduced into the market over the past few years, and an expanding range of new products are in the pipeline. Some of them are limited in their applications, working only in defined sites and planes of the soft tissue layers of the face. They all have short-term and long-term benefits as well as potential risks.

For plastic surgeons evaluating these products, staying abreast of the vast array of new fillers, the marketing information, the clinical reports, and the regulatory status can be an overwhelming task. The material that follows provides an overview of available products. For the purpose of this discussion, fillers will be classified in the following categories:

- Autologous materials
- Biologic materials
- Synthetic materials
- Off-label materials

Autologous Fillers

Autologous materials are derived from the patient's own tissue. They come closest to matching the description of the ideal soft tissue filler in terms of safety, but they are not as convenient to use as some other fillers. They have to be harvested from another site on the body, which may produce a scar, and the process of harvesting and then inserting these materials elsewhere requires a two-step procedure. Toxicity, allergenicity, immunogenicity, carcinogenicity, and teratogenicity are not issues, but there can be problems with infection, migration, inflammatory reactions, loss of persistence, and reproducibility. Autologous fillers include the following:

- Dermis, fascia, cartilage, SMAS, breast implant capsule
- Fat grafts
- Platelet-rich fibrin matrix (PRFM)

Dermal, fascial, and cartilage grafts have a long history of use in plastic surgery, and with careful handling and placement in an appropriate recipient bed, these grafts may produce very good, long-lasting results. Deepithelialized skin can be used to correct deficient contours on the nasal dorsum, depressed scars, and deficient facial outlines. Their bulk is increased by folding the graft onto itself, and it is recommended that no portion of the graft be more than 5 mm from the blood supply. When the re-

recipient bed is optimally vascularized and the “take” is successful, approximately 80% of the bulk of the graft will be maintained permanently. Less volume survives when lipodermal grafts are used, because it is the dermal surface that must derive the blood supply from the host and serve as a vascularizing carrier for the fatty elements. Similarly, fascial grafts from the fascia lata of the thigh, the temporalis, and the superficial musculoaponeurotic system (SMAS) can be used as slings or sheets to smooth nasal irregularities or fill facial contours. In a good recipient bed, fascia is permanent and persists through a combination of creeping replacement by host fibroblasts and continued viability of fascial fibroblasts. Although these autografts work well, they require incisions to harvest the tissue and must be used in sheets, strips, or tubes.

Fat grafts as free en bloc transfers of tissue have the disadvantage of losing at least half of their volume after transplantation, and cysts, calcifications, and necrotic lumps can develop. However, with the introduction of liposuction, a readily accessible semiliquid form of fat became available, which in turn gave rise to injectable autologous fat grafting. Along with correction of liposuction deformities, facial contouring with microfat grafts became very effective in the hands of some plastic surgeons. The principles of injectable fat grafting include harvesting small, intact parcels of fatty tissue as atraumatically as possible. The aspirate is refined to separate the viable cells from nonviable oil and cell debris and is then reinjected under gentle pressure by depositing small parcels of fatty tissue in tiny amounts along multiple tracts, as the needle is withdrawn. The purpose is to keep the fat near a blood supply for survival and integration. This can be time consuming, and there is significant edema in the short term as well as some loss of volume over the long term. The great advantage of fat grafting is that it is permanent if the fat survives. The disadvantages are the unpredictability of the survival, the need for a donor site, and the time required to process and inject the tissue.

Selphyl (Aesthetic Factors LLC, Princeton, NJ) is a new, patented system that allows the extraction of a platelet-rich (and growth factor-rich) fibrin matrix (PRFM) from the patient's own blood. This novel technology allows processing of blood in the office in a three-step procedure that includes centrifugation and takes approximately 20 minutes. The collected PRFM is then injected into the patient's wrinkles. Collection of a 9 ml blood sample provides 4 ml of PRFM. The development of collagen and dermal matrix increases over a 3-week period, and there is early evidence to suggest long-lasting wrinkle correction (up to 20 months). Possible applications include correction of nasolabial folds and glabellar lines, panfacial rejuvenation, and treatment of acne scars and other scars. Selphyl has been cleared by the FDA for use in the United States and in Europe with a CE mark. Although additional long-term data are still required to prove its efficacy, this product represents the first practical modality for collection of fibrin matrix as an autologous wrinkle treatment.

Biologic Fillers

Biologic materials derived from organic sources (humans, animals, or bacteria) offer the benefits of ready off-the-shelf availability and ease of use, but these introduce issues of sensitization to foreign animal or human proteins, transmission of disease, and immunogenicity. Often, as the tissue is processed to reduce these untoward side effects, the molecular structure is destabilized, resulting in lack of persistence at the recipient site. The focus in the past few years has been on finding new materials that are better tolerated, have greater longevity, and do not need prior skin testing to rule out sensitivity to animal proteins. Still, biologics provide only a temporary effect and typically do not completely correct the wrinkles or creases. The three major types of biologic tissue fillers are acellular soft tissue matrix, collagen, and hyaluronic acid products.

FDA-Approved Biologic Fillers

Filler	Type
Cymetra	Human dermis
AlloDerm	Human dermal matrix
Dermolagen	Human collagen matrix
Surgisis	Porcine collagen matrix
Fascian	Human tensor fascia lata
Zyderm/Zyplast	Collagen (bovine)
CosmoDerm/CosmoPlast	Collagen (human-based)
Restylane	Hyaluronic acid (bacterial)
Eleveess	Hyaluronic acid (bacterial)
Juvéderm	Hyaluronic acid (bacterial)
Hylaform	Hyaluronic acid (animal)

Cymetra (LifeCell Corp., Branchburg, NJ) is lyophilized acellular collagen matrix derived from human cadaver dermis. It is FDA approved for subcutaneous injection and is used for lips, nasolabial folds, and deep wrinkles and lines. It requires rehydration before injection, and there is no lidocaine in the product, although it can be added to the reconstituted product. Its longevity is reported to be about the same as that of bovine collagen.

Fascian (Fascia Biosystems, Beverly Hills, CA) is a preserved particulate human fascial graft that is marketed in syringes with different particle sizes ranging from 0.1 to 2.0 mm; it is injected through 14- to 27-gauge needles, depending on the particle

size. Prepared from prescreened human cadaver fascia lata, Fascian is freeze dried, irradiated, particulated, vacuum sealed, and stored at room temperature. It requires rehydration before use and is injected intradermally, subdermally, or in deep tissue, depending on the application. In some cases, native collagen may replace the fascial graft, and it is reported that Fascian particles tend to last two or three times longer than bovine collagen products. Use of the product is technique dependent, and lumpiness has been reported, as have rare local reactions and herpetic activation.

AlloDerm (LifeCell Corp.) is an acellular, structurally intact sheet of human dermal graft that was first used clinically in the treatment of full-thickness burns. Processed from prescreened human cadaver skin, the cells responsible for immunogenicity are removed; the matrix structure and biochemical components are left intact. The grafted material then acts as a template or blueprint for recipient cell repopulation, resulting in soft tissue regeneration. AlloDerm is supplied in freeze-dried, sealed foil packets in various sizes and thicknesses and is stable for 2 years with refrigeration. It has been available for several years as an implant for cosmetic and reconstructive soft tissue augmentation. Some of its applications include augmentation of the lips, correction of nasolabial folds, softening of glabellar wrinkles, rhinoplasty (dorsum and tip) as well as septal perforation, Frey syndrome, correction of defects from liposuction, and treatment of scars. Complications can include infection, persistent palpability or lumpiness, and variable take of the grafted material. Reports of volume diminution in mobile graft areas range from 30% to 40% at 1 year to 70% retention after 18 months.

Surgisis (Cook, Inc., Bloomington, IN) is a lyophilized collagen matrix that is porcine derived and marketed in sheets of various sizes and thicknesses. Although it is used as a fascial replacement, there is less information about its use for aesthetic applications at this time.

Bovine collagen, marketed as Zyderm and Zyplast (Allergan, Irvine, CA), became available in 1981 and is a unique product. It was the first commercially marketed injectable approved by the FDA for soft tissue augmentation; it has been used in millions of patients and is the standard against which all other injectables are compared. CosmoDerm and CosmoPlast (Allergan, Irvine, CA) contain human collagen and do not require a pretreatment skin test. Isolated and purified from human dermal tissue and grown under controlled laboratory conditions, the fibroblasts are screened for pathogens and the collagen is subjected to viral inactivation. Although the use of all the above collagens has been discontinued in Canada, they are still available for use in the United States.

Hyaluronic acid (HA) is a glycosaminoglycan common to most living organisms and is a component of connective tissue of the skin, cartilage, bone, and synovial fluid. In human skin, hyaluronic acid adds bulk and acts as a shock absorber and lubri-

cant. Hyaluronic acid binds water and after injection maintains a bulking effect as it is degraded, a process that has been called *isovolemic degradation*. Restylane (Q-Med Esthetics, Uppsala, Sweden) is a hyaluronic acid soft tissue filler that received FDA approval in December 2003 for use in the correction of facial wrinkles. It is marketed as three products that differ in the size of the constituent particles: Restylane Touch (Fine Lines), Restylane, and Perlane. Restylane Touch (Fine Lines) is available in Canada, but not in the United States. The Restylane products are manufactured by recombinant technology in bacteria, thus eliminating the need for skin testing. The shelf life of Restylane is 1.5 years, and its longevity is 6 to 12 months, depending on the location treated and the injection technique. Eleveess (Anika Therapeutics, Inc., Bedford, MA; FDA approved in 2006) contains higher concentrations of hyaluronic acid as well as lidocaine and is intended for medium wrinkles and deeper folds. Prevelle Silk (Mentor, Santa Barbara, CA) was introduced in the United States in 2008 and is equivalent to Restylane. In 2006 Allergan's Juvéderm series of hyaluronic acid fillers received FDA clearance. Juvéderm fillers come in various concentrations and viscosities. In Europe they are labeled as Juvéderm Ultra 2, 3, and 4 and Juvéderm Voluma; in North America they are marketed as Juvéderm Ultra and Juvéderm Ultra Plus. Formulations containing lidocaine are also available (Juvéderm Ultra XC and Juvéderm Ultra Plus XC). There are a large number of non-FDA-approved biologic fillers that are available in the rest of the world. These are mainly HA-based products with various sources, processing, and cross-linking.

Non-FDA-Approved Biologic Fillers

Filler	Type	Approved In
R-fine	HA	Canada, Europe, Asia
Hyaluderm	HA	Europe
Revanesse/ReDexis	HA (cross-linked)	Canada
MacDermol S/MacDermol R	HA (avian, cross-linked)	Europe
Varioderm	NASHA	Europe
Amalian	NASHA	Europe
Macrolane	NASHA	Europe
Teosyal	NASHA	Europe, Canada
Zetaderm/Zetavisc	NASHA	Europe, Canada, Russia
HydraFill	NASHA (cross-linked)	Europe
Esthélis/Fortélis/Belotero	NASHA (CPM technology cross-linked)	Europe, Canada, Asia
Puragen	NASHA (DXL technology cross-linked)	Europe, Canada
Rofilan/Piloderm/Beautygel/ Esthirase/Coilingel	NASHA (cross-linked)	Europe, Canada, Brazil
HyalSkin	NASHA (BDDE cross-linked)	Europe

BDDE, 1,4-butanediol diglycidyl ether; CPM, cohesive polydensified matrix; DXL, double cross-linked; HA, hyaluronic acid; NASHA, non-animal-stabilized hyaluronic acid.

Filler Characteristics*			
Filler	Category	Composition	Viscosity†
Zyplast	Biologic	Bovine collagen	++
Zyderm I and II	Biologic	Bovine collagen	+
CosmoPlast	Biologic	Human collagen	++
CosmoDerm	Biologic	Human collagen	+
Perlane, Juvéderm Ultra Plus, Puragen	Biologic	HA (bacterially derived)	+++
Restylane, Juvéderm Ultra, Elevers, Hylaform	Biologic	HA (bacterially derived)	++
Restylane Fine Lines	Biologic	HA (avian culture derived)	
		HA (bacterially derived)	+
ArteFill (Artecoll outside the U.S.)	Synthetic/biologic	Polymethylmethacrylate (PMMA) beads covered with bovine collagen	+++
Radiesse	Synthetic	Calcium hydroxylapatite	+++
Sculptra	Synthetic	Poly-L-lactic acid (PLLA)	++

*Table courtesy Lisa Airan, MD.

†Viscosity is not measured by most companies in terms of flow: + = Least thickness, easiest/best flow; ++ = In between; +++ = Most thickness, more difficult flow.

‡Level of placement is also dependent on amount/type of desired correction.

HA, Hyaluronic acid.

Level of Placement‡	Advantages	Disadvantages and Complications
Superficial to deep dermis	Less swelling (~24 hr); easy to use	Skin test required; more inflammatory; very short-term correction
Dermoepidermal junction	Less swelling (~24 hr); easy to use	Skin test required; more inflammatory; very short-term correction
Superficial to deep dermis	Less swelling (~24 hr); less inflammatory; easy to use	Length of correction variable
Dermoepidermal junction	Less swelling (~24 hr); less inflammatory; easy to use	Short- and long-term correction
Deep dermis	Long lasting; can be used in deep tissue and along bone; minimal reactions; no skin test needed	More swelling—up to 3 to 5 days
Superficial dermis	Long lasting; can be used in deep tissue and along bone; minimal reactions; no skin test needed	More swelling—up to 3 to 5 days
Dermoepidermal junction	Excellent for use in glabellar region and fine lines; do not use along bone	Shorter term longevity than Restylane or Perlane
Deep dermis or subcutaneous	Long lasting in deep folds and acne scars	Requires skin test; associated with bumps, which may require treatment with steroids or surgery to remove; risk of granuloma; collagen reactivity
Deep dermis or subcutaneous	Long lasting; can be used in deep tissue and along bone; minimal reactions; no skin test needed	More swelling—up to 3 to 5 days; irregularities (technically dependent)
Deep dermis or subcutaneous	Long lasting; can be used in deep tissue and along bone; minimal reactions; no skin test needed	More swelling—up to 3 to 5 days; irregularities (technically dependent); inflammatory reactions; multiple treatments required

Synthetic Fillers

Synthetic materials can offer permanence. Many injectable and surgically implantable synthetic products have been used over the years, and many have been condemned for such complications as granulomas, acute and delayed infections, migration or displacement, and deformities that can result from complications or removal of the material. It is with these products that the difference between the regulatory process in the United States and that in the rest of the world is highlighted. The FDA controls access to the U.S. market and enforces strict labeling practices, which means that the manufacturer must spell out the exact applications for which the material has been approved. Although a number of products have been available for years in Europe, South America, and Asia, only ArteFill (Suneva Medical, Inc.), a polymethylmethacrylate (PMMA)-containing product, is marketed in the United States for permanent facial augmentation. ArteFill is FDA approved for use in the correction of nasolabial creases. Several other permanent synthetic fillers, such as Bioplastique (Uroplasty BV, Netherlands), are in clinical trials in the United States. Synthetic fillers approved by the FDA are listed in the table below.

FDA-Approved Synthetic Fillers	
Filler	Type
AdatoSil 5000	Silicone
Silikon 1000	Silicone
ArteFill (Artecoll)	Polymethylmethacrylate (PMMA)
Radiesse	Calcium hydroxylapatite
Sculptra (NewFill)	Poly-L-lactic acid (PLLA)

AdatoSil 5000 and Silikon 1000 are silicone gels with improved viscosity that have been approved by the FDA for use in treating detached retinas. Although they are permanent, they are not approved for cosmetic use in the United States, and caution is advised with these products. Historically, injectable silicone products have tended to harden, migrate, and cause inflammation and skin necrosis. Bioplastique is composed of solid silicone microparticles (100 to 400 microns) that have been vulca-

nized, texturized, and placed in a polyvinylpyrrolidone carrier. Injected dermally, the carrier is resorbed and the silicone microparticles are encapsulated in host collagen, which prevents migration and effects permanent correction. It is used in many parts of the world but is not approved by the FDA for use in the United States because of concerns about granulomatous reactions and permanent lumps that can be removed only through surgery.

ArteFill is a permanent injectable implant consisting of polished polymethylmethacrylate (PMMA) microspheres suspended in bovine collagen in a 20% to 80% ratio. After injection, the collagen is resorbed and the round, smooth microspheres are encapsulated by host collagen where they are stabilized and become permanent. Used in Europe for the past decade as Artecoll, ArteFill was approved by the FDA in October 2006.

Radiesse is a mixture of calcium hydroxylapatite (30%) and polysaccharide gel (70%). The polysaccharide gel is very white, which makes Radiesse inappropriate for use in the dermis. At present, Radiesse is FDA approved (December 2006) for nasolabial and labiomental crease correction. Potential concerns about its use as a soft tissue filler include clumping, lumping, granulomas, and migration of the microspheres. It is reported to last from 1 to 2 years.

Sculptra is composed of poly-L-lactic acid (PLLA). Because it is not made from human or animal sources, it does not require a skin test. PLLA is a biocompatible, biodegradable material that has been used in surgical products for more than 20 years as a component of dissolvable sutures. Sculptra has been safely used outside the United States since 1999 in more than 30 countries under the trade name of NewFill for a variety of facial volume and contour deformities. It was approved by the FDA in August 2004 as the only product for the correction of HIV-associated facial lipoatrophy and was approved in 2009 for cosmetic use in the United States. It is injected subcutaneously in the area of fat loss/volume loss and provides a gradual and significant increase in volume. It is reported to last up to 2 years after the third treatment session.

A large number of other synthetic fillers are available in various parts of the world; a few of these are listed in this chapter. It is difficult to comment on the effectiveness and safety of these products, because results of clinical trials using these products have not yet been reported in the literature.

Non-FDA-Approved Synthetic Fillers

Filler	Type	Approved In
Bioplastique	Silicone	Europe
Aquamid	Polyacrylamide	Europe and 40 countries worldwide
Beautical	Polyacrylamide	Europe
Bio-Alcamid	Polyacrylamide	Europe
Outline	Polyacrylamide	Europe
Evolution	Polyacrylamide	Europe
Formacryl	Polyacrylamide	Russia
Argiform	Polyacrylamide	Russia
Bioformacryl	Polyacrylamide	Ukraine
Amazing Gel	Polyacrylamide	Asia
DermaLive/DermaDeep	Polyacrylamide	France
Metacril	Methylmethacrylate	Brazil
ArteSense	Methylmethacrylate	Europe, Canada, Asia
Arteplast	Methylmethacrylate	Discontinued
Rhegecoll	Methylmethacrylate	Pending worldwide
Laresse Dermal Filler	Carboxymethylcellulose/ polyethylene	Europe
Atléan BTCP	Tricalcium phosphate	Europe
Bioinblue	Polyvinyl alcohol	Europe
Reviderm	DEAE Sephadex	Europe, Canada, Asia
Matridex	DEAE Sephadex	Europe

BTCP, Beta tricalcium phosphate; DEAE, diethylaminoethyl.

Off-Label Use of Fillers

“Off-label” use of synthetic materials is technically possible but does carry some risk. A number of synthetic fillers are approved for use for conditions unrelated to plastic surgery. For example, AdatoSil silicone oil and Silikon 1000 are used for tamponade of retinal detachment. Such products are available, clearly approved for other soft tissue applications, and can be purchased and used off-label to treat wrinkles or augment the face. But is this wise? The manufacturer is strictly prohibited by the FDA from advertising or promoting off-label use and can incur stiff penalties for doing so. The plastic surgeon is not subject to these FDA controls but is vulnerable from a liability standpoint and would have a difficult time defending the use if the product does not perform well.

THE ART OF SCULPTING WITH INJECTABLE FILLERS

Soft tissue fillers have provided aesthetic surgeons with an effective means of addressing patient requests for nonsurgical facial, hand, and body rejuvenation. Today a plethora of excellent products are available that are appropriate for filling, augmenting, and recontouring. However, as with any aesthetic product or procedure, success depends on an understanding of the specific applications for the material and the technical nuances to ensure that these materials are used appropriately. Therefore this section will serve as a primer for using the commonly available injectable fillers. It will provide specific information on the following:

- Product characteristics and composition
- Indications and applications
- Injection technique
- Average volumes used in each area
- Level of placement
- Ease of injection
- Combinations
- Longevity
- Adverse effects, reactions, and complications
- Results

Hyaluronic Acid Products

We begin our discussion by focusing on hyaluronic acid products because of their widespread popularity and range of applications. The viscoelastic properties, stabilizing role, and protective action on cell membranes afforded by hyaluronic acid make it an ideal material with which to fill skin depressions. Approval for use in Canada was granted in 1998, and very quickly hyaluronic acid products surpassed collagen to become the new benchmark for soft tissue fillers. Approval in the United States was granted in late 2003.

Medicis, Allergan, Biomatrix, Anika Therapeutics, and Mentor are five of the companies offering approved hyaluronic acid products in the United States. Other companies, such as Anteis, have new products in use in Europe and Canada, but these are awaiting FDA approval. To offer the most appropriate fillers for different types of wrinkles and skin, these manufacturers generally offer several products with different viscosity and particle sizes.

Features

The three products available from Medicis are Perlane, Restylane, and Restylane Fine Lines/Touch. As mentioned above, the latter is available in Canada (Restylane Fine Lines) and Europe (Restylane Touch), but not yet in the United States. These products are composed of hyaluronic acid and differ from each other in molecular size. Perlane is the largest hyaluronan, and Restylane Fine Lines/Touch is the smallest. Indications for the level of placement in the tissue depend on the particle size. Perlane is injected at the deepest level in the deep dermis or subcutaneous tissue; Restylane is injected in the mid-dermis, and the needle should not be visible; and Restylane Fine Lines/Touch is injected at the dermal-epidermal junction. The Restylane injectables are non-animal stabilized hyaluronic acids (NASHAs).

Allergan's Juvéderm is another hyaluronic acid product. Juvéderm is available in different concentrations and viscosities: 18 mg/ml, 24 mg/ml, and 24 mg/ml high viscosity (HV), 30 mg/ml, and 30 mg/ml HV. In the United States and Canada, Juvéderm is available in 24 mg/ml HV (Juvéderm Ultra) and 30 mg/ml HV (Juvéderm Ultra Plus). Formulations with 0.3% lidocaine (Juvéderm Ultra XC and Juvéderm Ultra Plus XC) are also available, helping decrease the pain and discomfort that is often associated with filler injection. Juvéderm Ultra Plus is more cross-linked than Juvéderm Ultra, thus making it more viscous; it is intended for use in deeper folds. Juvéderm, similar to the Restylane group of fillers, is produced in bacteria and then purified.

Prevelle Silk, a lidocaine-containing formulation of hyaluronic acid produced by Mentor, has recently become available in the United States. Mentor's Puragen is a similar product with higher cross-linking; it is intended for injection in the deep dermis. Puragen is available in Canada and is not yet approved by the FDA.

Eleveess (Anika Therapeutics, Inc.) has the highest concentration of hyaluronic acid (28 mg/ml) and contains 0.3% lidocaine, offering peri-injection analgesia. Eleveess is also derived from bacteria and thus its injection results in virtually no hypersensitivity reactions.

Esthélis Soft, Esthélis Basic, and Fortélis Extra, produced by Anteis (Geneva, Switzerland), are hyaluronic products analogous to Restylane Fine Lines/Touch, Restylane, and Perlane, respectively, and are in use in Europe and have recently become available in Canada. These fillers are not FDA approved at present.

Indications and Applications

Hyaluronic acid fillers are useful for deeper folds, lips, and irregularities such as soft acne scars, nasal deformities, and areas that require more sculpting. One of the main indications for hyaluronic acid is augmentation of the lips. These tissue fillers are also useful for augmentation of the nasolabial folds, marionette grooves, the mental fold, and the hollow of the anterior jowl line. Overall complete facial sculpting may be performed with combinations of these products. Perlane/Juvéderm Ultra Plus/Puragen can be used interchangeably with Restylane/Juvéderm Ultra/Prevelle Silk/Elevess in most situations, and the larger particle sizes yield better longevity. Less bruising may result if these tissue fillers are injected as the needle is advanced.

In the subsequent discussion, we will refer to Restylane, but Juvéderm Ultra or Prevelle Silk could also be used in the same manner.

Restylane

Restylane represents the middle-sized particles of hyaluronic acid products produced by Q-Med. It differs from Juvéderm in that it is made up of particles of hyaluronic acid molecules, whereas Juvéderm is a syrup. Restylane has a lower level of cross-linking and a lower level of reported foreign protein. It is provided in 1.0 cc syringes with a 30-gauge needle. Restylane can be used in many areas of the face and brow

with excellent longevity. Because it can be molded and massaged to a degree, precise results can be achieved with minimal complications. Prevelle Silk is similar to Restylane but contains anesthetic, requiring anterograde injection.

Indications and Applications

Restylane can be injected in the lips, nasolabial folds, glabellar creases, forehead lines, infraorbital and supraorbital hollows, and temporal hollows. It can also be used to raise the eyebrows, soften the chin fold, correct scars from acne or traumatic injuries, improve nasal deformities, and reconstruct contour deformities arising from trauma, reconstructive surgery, or acquired soft tissue atrophy syndromes. As previously mentioned, it is often combined with Restylane Fine Lines/Touch and Perlane to achieve the best results.

Lips

Contouring the lips may be accomplished with Restylane alone or with Restylane in combination with other fillers. However, Restylane on its own produces an excellent result. The procedure may be carried out using infraorbital and mental nerve blocks (separate block for the corners of the mouth) or with topical anesthetic. Direct infiltration of the tissues with lidocaine with epinephrine may also be done to limit the degree of bruising.

Center: 1, The vermillion border is enhanced to define the shape of the lip. 2, The Cupid's bow (philtral columns) is narrowed with injection. 3, The site of injection from the wet-dry junction to the vermillion border is used to increase lip show at the lateral aspects. 4, Restylane is injected posterior to the wet-dry junction to enhance lip projection.

Ideal candidates have a good shape to their lips to begin with. In these patients, just augmenting the vermillion is enough to produce an excellent result. In addition, proper dental occlusion aids in getting a more symmetrical result. The left and right sides of the lips differ in length and thickness; this must be observed and demonstrated to the patient before augmentation. Achieving symmetry can be a challenge, but the patient should be aware of these pretreatment asymmetries so expectations for improvement are realistic.

In patients with long, thin lips, results may be limited because of tissue tension. For patients with lips that are tight to the dentition or who have a class II occlusion, aug-

mentation volumes should be conservative, because irregularities of dentition may be reflected in the upper lip and will appear too prominent or “ducklike.” Scars may not respond to the volume addition and can leave an irregularity. The Cupid’s bow becomes wider with age and should be made narrower (see 2 on the center photo). The depth of the mental fold increases with age and may require softening; it can add to the result of the lip contour. Patients with a history of herpes should be given prophylactic treatment, because the procedure may cause a herpetic outbreak and scarring.

Augmentation in patients with long, thin lips and very broad smiles is difficult. Often patients complain that their lips are too thin when they smile; this is a dynamic change that cannot be corrected with fillers or implants. The physician must clearly explain that the result these patients desire may not be achievable with one or even subsequent injections, no matter what product is used.

INJECTION TECHNIQUE AND LEVEL OF PLACEMENT When Restylane is used for lip augmentation, the injection process generally starts with augmentation of the vermilion border of the lip to enhance its definition and provide increased projection. The philtral columns may also be augmented, and the placement of Restylane at this level is usually in the mid-dermal level and for the vermilion border is along the “pseudotunnel” of the lip border. Restylane must not be placed too superficially, because it will appear as a light blue color (Tyndall effect). Palpation of the tissue as the Restylane is injected is important. Occasionally it can track in a direction perpendicular to the direction of injection as a result of weakness in the tissue and the vertical lip lines. If this occurs, the Restylane needs to be massaged immediately to eliminate this irregular contour.

Injection of the lip proper from the wet-dry junction to the vermilion border may also be carried out at a level that is just deep to the mucosa within the orbicularis oris muscle. If it is placed immediately beneath the mucosa, it will appear blue. Placement posterior to the wet-dry junction along the wet mucosa may enhance the lip volume as well as the projection. Again, the depth of the injection is below the orbicularis oris muscle to make the product undetectable. Placement of the product must be varied, depending on the desires of the patient and the starting shape of the lips. Care must also be taken to observe any previous asymmetries, scars, weakness, herpetic infections, dentition (including occlusal classification), the length of the philtral column and upper lip, the width of the Cupid’s bow, and the depth of the mental fold, all of which can affect the results. Photographs should always be taken before the treatment and discussed with the patient, along with a full explanation of the potential risks and benefits for all injections.

VOLUMES Approximate volumes for augmentation of the lips may range from 0.5 to 1.0 cc per lip with Restylane. There may be immediate swelling with the placement due to the trauma of needle, bruising, or immediate swelling from Restylane

absorbing water. Immediately after injection, the lip size should be equivalent to the final result; however, some patients develop swelling from bleeding and needle-stimulated histamine release. In the patients who develop immediate swelling, lip shape will be consistent with final results from days 3 to 5. The lips will not increase in size beyond the volume placed. If subsequent injections are indicated, less volume may be required to achieve the desired correction.

LONGEVITY Longevity is dependent on the metabolism of the individual as well as the amount of movement with animation. In general, patients who are more animated have a shorter duration of filler. The filler remains in the tissue for up to 16 months, although with diminished intensity. For most individuals, more augmentation may be achieved at secondary and tertiary injections, which build on the remaining filler. This allows for further shaping, enhancement of volume, and contouring of the lips when subsequent injections are performed. The filler should last for a period of 4 to 6 months; however, when it is repeated, the results may last for 8 months up to 1 year. In some individuals, the filler may disappear after as short a period of time as 3 months and require repeat contouring. Juvéderm and Prevelle have similar longevity to Restylane.

EASE OF INJECTION For the lips, Restylane is more difficult to inject than collagen because of the higher viscosity of the material and the same-sized needle (30-gauge). Use of Restylane may result in more bleeding or bruising, which needs to be controlled during the injection process to limit the extent of bruising after injection.

TECHNICAL NUANCES Care must be taken to inject Restylane with an even flow and movement of the needle so that it does not deposit as lumps or bumps in the tissue. If lumps or bumps are detected, they must be massaged out immediately. Preexisting asymmetries should be corrected when possible. Care must be taken to balance the projection of the upper and lower lips so that a ducklike deformity does not result.

Frequently the upper lip is atrophied above the vermilion border, particularly the lateral aspects; restoration is done with Restylane placed at the mid-dermal level to improve volume and projection of the upper lip. One should use minimal volume in the upper lip above the vermilion border, because any added volume may cause lengthening of the upper lip. (It can push the upper lip farther down over the upper dentition.) Care must be exercised to limit the amount of filler placed in the upper lip skin adjacent to the nasolabial fold, because excess infiltration will result in awkward animation of the upper lip and nasolabial fold, particularly when the individual is smiling, and can give the appearance of a “joker-type” upper lip or create an unusual fold at the lateral edge of the upper lip.

If the patient has implants, the filler may be added around the implant without removal unless the patient desires this. The risk of infection is minimal but is still pres-

ent. If the patient wants the implant removed, filler may be added at the same time as the removal, with a plan for the patient to return for reassessment.

COMBINED TREATMENT Some physicians combine Restylane injections with that of other tissue fillers. Collagen may first be injected along the vermilion border, which provides local anesthesia and augmentation of the white roll. Restylane Fine Lines/Touch may also be used to enhance the white roll; however, Restylane itself works very well in this area. The individual vertical lines of the lips may be corrected with Restylane Fine Lines/Touch or collagen injection.

Restylane can also be used with *botulinum* toxin. In this situation the neurotoxin may be used in the upper and lower lip orbicularis oris muscle to limit the pinching of the lip and the formation of vertical lip lines. The amount of *botulinum* toxin will vary, starting with 2 units per side in the upper lip, avoiding the midline, and up to 3 or 4 units per side in the upper and lower lip. Rarely, after neurotoxin injection in the upper lip, patients have difficulty with pronunciation of *P*'s and *B*'s and an inability to drink through a straw or out of a cup. If this occurs, the patient may do active puckering of the lips for 15 minutes at a time, several times a day, to help alleviate these symptoms. *Botulinum* toxin will help prolong the longevity of the Restylane in the lips and will increase lip projection and shape. The neurotoxin may be placed at the vermilion border or approximately 5 mm from the vermilion border. It must not be placed too far away from the vermilion, which will result in diminished shape of the lips. The closer the neurotoxin is placed to the vermilion border, the greater the lip projection. Restylane may also be placed in areas where ArteFill (Artecoll) has been placed previously after a minimum waiting period of 2 to 3 months.

Nasolabial Folds

As with the lips, the nasolabial folds may be of different shapes, lengths, and depths. Some patients have preexisting telangiectasia that can be made worse with injections. The classification system described by Lemperle is useful in evaluating patients and discussing their goals.

Lemperle Nasolabial Fold Classification

Class	Description
0	No wrinkles
1	Just perceptible wrinkles
2	Shallow wrinkles
3	Moderately deep wrinkles
4	Deep wrinkles, well-defined edges
5	Very deep wrinkles, redundant folds

The amount of change in the average patient should be approximately 50% correction of the depth of the fold. Restylane can be used to soften the broader portion of the fold, which is usually the upper two thirds down to the lateral oral commissure. The product is placed at the level of the mid- to deep dermis. If the nasolabial fold has a superficial line etched into it, this can be softened with Restylane Fine Lines/Touch. Alternatively, Perlane may be used in place of Restylane. The product is placed at angles to the fold, and layering may be done to enhance longevity. Also, Perlane may be placed deep to the Restylane for the very deep folds. When Perlane is used instead of Restylane for correction of the nasolabial folds, the difference in longevity may be slight with the Perlane lasting longer. As with all repeated injections of hyaluronic acids, the product lasts longer and less volume of product is needed to achieve the same volume and contour change. Care must be taken not to overfill the fold because this will give patients an odd appearance when they animate or smile. Taping of the fold after the injection for a few days allows the product to be bound into place with scar tissue and can prevent the lateral displacement of the product to the nasolabial fold when the patient smiles.

VOLUMES Fold depth is variable; thus the amount of filler may range from as little as 0.5 cc to as much as 1.5 cc of Restylane or Perlane. Complete correction of the fold on the first visit is not recommended because this may give the fold an unnatural appearance. For the first-time treatment, the patient should be instructed that the fold will initially be corrected by filling one half of the depth and further correction will be done at a subsequent injection. This is done to avoid overcorrection; excessive filler placed at one time can cause telangiectasia. This approach has several benefits: it keeps the patient's expectations at a reasonable level, the degree of change is not too drastic, and the fold does not feel as firm. It allows precise correction of the fold depth and avoids overcorrection, particularly at the lower third of the fold. If too much dermal filler is placed in the fold that overlies the dentition, then it may appear as a bump. This is particularly true of the fine but deep marionette lines lateral to the commissure.

Scars and Deformities

Many deformities of soft tissue can be corrected with Restylane. It is important that the scar/tissue be soft and distensible. The product should not be placed under high pressure, because this may result in tissue necrosis. More than one treatment may be required for full correction. Excellent results can be achieved in acne scars, chickenpox scars, and traumatic scars, and these can be very long lasting. Simultaneous release of the scar with an 18-gauge needle may improve the results. The use of Restylane Fine Lines/Touch for the treatment of steroid atrophy is helpful, but it must be used with caution, because the atrophy may be permanent. The patient should be warned of this so that residual atrophy is not attributed to the use of the hyaluronic acid.

VOLUMES AND TECHNICAL NUANCES The volumes may be variable. Very small amounts (0.05 cc) are needed for acne or chickenpox scars; these are placed at a superficial level (dermal-epidermal junction). For larger soft acne scars, up to 0.2 cc is placed at the mid- to deep dermis. Layering of the fillers may be needed but not commonly. The use of *botulinum* toxin in conjunction is helpful for scars located in mobile areas such as the glabella, forehead, and chin, where the mimetic action may be reduced. This may also increase the longevity of the filler. Restylane can be injected with a 32-gauge needle in lieu of Restylane Fine Lines/Touch for fine scars. Care must be taken with the amount of pressure applied to the plunger and the needle being firmly attached to the syringe.

Glabellar Folds

The folds of the glabella are ideally treated in combination with *botulinum* toxin. If the fold is easily effaced, the neurotoxin may soften the fold on its own. The glabellar fold may be a fairly superficial line with a deeper etched component that is best treated with Restylane Fine Lines/Touch at the dermal-epidermal junction; the filler is placed in a pinpoint manner and with serial linear injections at the same level, thereby undermining the line and placing the filler in a crisscross fashion. If the fold is broader, Restylane may be used; this is placed at the mid- to superficial dermis with a linear threading technique. Small amounts must be injected to avoid tissue necrosis. When combined with *botulinum* toxin, the effect can last from 8 months to much longer as a permanent correction. This area tends to have deep, dilated pores; occasionally some filler is lost in the pore, and it is difficult to achieve complete correction.

VOLUMES A range of 0.2 to 0.4 cc of Restylane and up to 0.2 cc Restylane Fine Lines/Touch may be needed for correction of the fold. Layering of these fillers may be needed on occasion. Care should be taken in a patient with very thin skin, because the filler may cause lumps or bumps.

Forehead Lines

The injection technique in this area is similar to that used for glabellar lines. If the patient has a very dynamic forehead, *botulinum* toxin will be very helpful in achieving a better result and increasing the longevity. If neurotoxin is not used, the filler may last for only a short period. Caution with the neurotoxin should be exercised in patients with moderate to severe brow ptosis. More commonly, Restylane Fine Lines/Touch is used and is placed at the dermal-epidermal junction by pinpoint placement or in a linear threading technique.

VOLUMES Volumes will vary markedly, anywhere from 0.2 to 0.8 cc of Restylane Fine Lines/Touch. Restylane may be used for the deeper and broader folds.

Eyebrows

The eyebrows may be elevated 1 to 2 mm by the addition of Restylane to the deep tissue layer of the lateral eyebrow. The volume of the temples generally decreases with age, and the placement of 1 cc of Restylane on the deep layer will help restore the youthful contour and raise the eyebrow. Surgical removal of the fat of the upper eyelid is sometimes done to such a degree that it results in a hollow or skeletonized orbital rim, or this characteristic may be seen in some individuals as a consequence of the aging process. The hollow appearance may be corrected by placing Restylane on the inferior aspect of the supraorbital rims. This also gives the illusion of raising the eyebrows while restoring a more youthful appearance to the upper lid and eyebrow region.

VOLUMES AND LEVEL OF PLACEMENT Volumes may range from 0.2 to 0.5 cc per side. A similar volume for the hollowed orbit can be used. In these two areas the filler can be molded to achieve a high-quality result with minimal risk. Care must be taken to inject small volumes with each pass to prevent emboli and injury to the sensory nerves. The filler is placed at the level that is not mobile. Caution is necessary in the central eyebrow, where the supraorbital nerves emerge.

LONGEVITY Restylane is a good deep filler; Perlane is a longer-lasting alternative and is used in a similar fashion. With the product placed on the deep layer, the longevity is increased to 6 months to 1 year, because where there is no movement, there is no displacement of the product.

Facial Lipoatrophy

Restylane and Perlane are ideal fillers for softening the appearance of lipoatrophy associated with antiretroviral therapy for HIV. The areas that are best treated are the concavities adjacent to the zygomatic-temporal bone, the zygomatic arch, and to a lesser degree, the inframalar hollow. In the temple and adjacent to the arch, it is important to place the filler deep within or under the periosteum, taking care to inject slowly to ensure even placement and minimize bruising. The product is easily massaged, but if massaging is too aggressive, the entire effect will be minimized. The injector should not completely fill the entire area of atrophy but should use a limited volume to soften the contours so that the wasting does not appear too severe. For the inframalar hollow, the goal of correction should be kept to a third to a half of the hollow. Linear threading or a fanning technique may be used to achieve a gradual, consistent result.

VOLUMES On average, volumes of 0.5 to 1.5 cc per area may be used. This will vary among individuals, depending on their requested goals. Repeat injections on a 2- to 4-week basis may help to contour areas that have a large volume deficiency.

Comparison of Restylane With Other Fillers

For the lips, Restylane is more difficult to inject than collagen because of the increased viscosity of the material and the larger needle size (30-gauge). Use of Restylane may result in more frequent bleeding or bruising, which needs to be controlled during the injection process to limit the extent of postinjection bruising. Collagen, in comparison, will cause minimal swelling and a smaller needle is used, therefore limiting the bruising. Restylane is easier to inject than ArteFill and has less associated bruising (a smaller needle [30-gauge] is used, compared with the 27-gauge for ArteFill), because it is less viscous.

Restylane Fine Lines/Touch is a softer product and much easier to inject than Restylane. Once injected, it can be molded very easily, thus making it more useful for superficial injection than Restylane. Perlane has a larger molecule and is firmer than Restylane. It does not flow as easily through the tissue despite the larger needle (27-gauge). Perlane can be used instead of Restylane in many cases. Restylane gives a more subtle result and is better used in individuals with more delicate tissues and fine features.

Postinjection Care

Postinjection treatment includes cooling with ice packs, 20 minutes on, 20 minutes off, for the first 24 hours, and oral administration of antihistamines (Claritin, Zyrtec, or Allegra in usual daily doses; these may be taken before the treatment). Oral supplements such as *Arnica montana*, bromelain, and others may help with bruising. The patient should be informed that swelling will occur in the first 3 to 5 days after injection, which may make the lips appear overdone. This will resolve, and there is possible bruising that could last up to 1½ weeks. There is initial swelling, which almost invariably is of concern to the patient immediately after the injection and for the first 3 to 5 days as he or she becomes accustomed to the new size and loses some volume (particularly with the first injection). If a local anesthetic or a nerve block is used, there will be some muscle paralysis, which creates asymmetrical movement and may make the lips appear to be completely asymmetrical. The patient should be alerted in advance to this possibility. Even with the advance warning, the patient will still question the symmetry after the injection. Augmentation is difficult in individuals with long, thin lips and very broad smiles. Care should be taken in providing adequate consultation and information that the result they desire may not be achievable with one or even subsequent injections. The patient is seen 1½ to 2 weeks after the initial injection to assess for any irregularities, lumps, bumps, or asymmetries. If a bump is discovered, it may be physically massaged down. If this does not alleviate the irregularity, hyaluronidase may be injected if available.

ADVERSE EFFECTS, REACTIONS, AND COMPLICATIONS When larger volumes of filler are injected at the same setting, a sterile abscess may occur that will require drainage. This may happen up to 1 to 2 weeks after the initial injection. The abscess is treated with local incision and drainage using an 18-gauge needle. Immediate drainage of clear fluid mixed with yellow-white debris resolves the problem, with rapid resolution of the symptoms.

Other complications that may occur are lumps, bumps, and irregularities, numbness of the lip, pain, hematoma, and overcorrection. Uncommonly, the patient may experience intermittent swelling in the treated region. This usually resolves 2 to 6 weeks after injection. Occasionally an individual will have massive swelling in response to the injection, and use of a Medrol Dosepak may be considered to alleviate this immediate swelling. The risks associated with steroid use should be explained to the patient. If he or she has preexisting telangiectasia or rosacea, more telangiectasia may develop, and this should be discussed before injection. This is particularly common at the nasal base for nasolabial fold correction.

Rarely, individuals may develop erythema of the overlying skin for the first several weeks. Clinically it does not behave like an allergy. A light topical steroid may be used as an initial treatment. In general, this reaction resolves without therapy over a short period. Even rarer is embolization of a vessel with necrosis of the tissues. Immediate blanching of the tissues is a bad sign and should be treated with massage, warm compresses, nitropaste, and if needed, hyaluronidase to remove the hyaluronic acid.

Results

This 51-year-old woman requested lip augmentation. Restylane was injected into the vermilion border (1) and philtral columns (2) to achieve a narrower appearance. The Restylane was injected from the inside of the lip from the vermilion border to the wet-dry junction (3). She is shown 3 months after injection with good persistence of the filler. This patient is a good candidate for treatment with Restylane and maintains good volume correction for 6 to 7 months, requiring less volume when she returns for a touchup with Restylane. With care, irregularities can be avoided. The patient was started on acyclovir for herpes prophylaxis.

This 30-year-old woman had concerns about the irregular appearance of her nasal tip cartilage. Restylane was used to fill in the hollows and shape the tip of her nose. Restylane 0.4 cc was used to soften the appearance of the nasal cartilage. The patient had inquired initially about rhinoplasty with tip alteration. She had not had previous surgery, and the nasal tip had not changed other than the irregularity becoming more noticeable with time. The skin at the tip of the nose was very thin, and any slight surgical irregularity may have been noticeable; additionally, the skin may have been compromised by an open rhinoplasty. The new tip contour was achieved under a block with local anesthetic and Restylane 0.4 cc in the office in 10 minutes. It took 5 days for the patient to recover, and she has shown persistence of the contour for more than 5 months. She is seen 5 months after injection (*far right*).

Perlane

Indications and Applications

Perlane is a very good filler for the deeper folds of the face. These include the nasolabial folds, deep marionette lines, and the hollow adjacent to the jawline along the jawline as shown (comparable products include Eleveess and Juvéderm Ultra Plus). Perlane is also an excellent filler for use in the periorbital region to soften the nasojugal groove as well as the periorbital hollow and can be used to achieve a “nonsurgical eye lift” (see p. 357). It must not be placed at the superficial or mid-dermis level, because there will be a light reflection off the material, giving it a blue color. Also, a superficial injection may cause irritation to the skin, resulting in local redness and swelling.

Lip Augmentation

Perlane may be used as an alternative to Restylane for lip augmentation and contouring. Perlane can be placed along the vermilion border and along the wet-dry junction of the submucosal plane or the intramuscular injection plane. It is best used in patients with lips that are not very mobile, because the material is stiffer than Restylane and will not allow proper movement of the lips if larger volumes are used. Care must be taken in using Perlane for persons with soft, supple lips that move a lot with animation; these patients may not respond well to Perlane augmentation, and their lips may appear too stiff.

LEVEL OF PLACEMENT AND INJECTION TECHNIQUE Perlane is placed in the deep dermal layer with a 27-gauge needle. When injecting Perlane, one must avoid the formation of lumps or bumps, because these are difficult to massage out of the tissue. With the larger needle size in comparison to that used for Restylane, there is a greater chance of bleeding and bruising.

VOLUMES For the lips, volumes may range anywhere from 1.0 to 2.0 cc with excellent results. Occasionally an individual may need less or more; the remainder may be placed in other areas, such as the nasolabial folds. For the marionette grooves, 0.5 to 1.0 cc per side may be used.

Deep Tissue (Periorbital and Jawline Contouring) Augmentation

In the areas along the jawline (filling the hollow anterior to the jowl) and in the periorbital region (nasojugal groove and periorbital hollowing), Perlane is best placed on the very deep plane on the bone (beneath the periosteum) to augment the soft tissues similar to a solid implant. Perlane (or Restylane) may be used as a nonsurgical option instead of microfat grafting.

VOLUMES FOR THE JAWLINE The volume may range from 0.5 to 1.5 cc per side. Placement of the material in the deep dermis may be required for complete correction of a jowl deformity.

VOLUMES FOR THE PERIORBITAL HOLLOW AND NASOJUGAL GROOVE The volume will range from 0.5 to 1.5 cc, depending on the extent of the desired projection of the cheek and malar region. This region is difficult to overcorrect, and with the material being placed on the deep layer, it can be massaged down for a relatively long time after the injection (2 to 3 weeks).

TECHNICAL NUANCES It is important to mark the patient before injection of the local anesthetic and to wait for at least 10 minutes to allow for the epinephrine effect to take place. Perlane is placed in the deepest point of the hollow on the bone; this will correct most of the deformity. When the needle is passed through the skin down to the bone, it is advanced along the bone, placing small amounts of Perlane along the depth of the hollow. The injector must watch for immediate bleeding and swelling. Pressure is applied to prevent a large bruise. After the correction is complete on one side, the patient should be shown the result with the mirror. Patients are immediately impressed with the dramatic improvement.

Nasolabial Folds

Correction of the nasolabial fold with Perlane is similar to correction of this area using Restylane. The exception is a deep nasolabial fold that extends past the commissure inferiorly. Care must be taken in this area when estimating the amount of Perlane to be placed; too much may make the tissues appear stiff (particularly during smiling) and can create a peculiar appearance.

VOLUMES In the nasolabial folds, the volumes may vary from 0.5 to 1.0 cc per side, depending on the depth of the fold. Very deep nasolabial folds or severe nasolabial folds are very difficult to correct and will not respond any better to Perlane than to Restylane, collagen, or ArteFill.

LONGEVITY Perlane lasts from 6 to 8 months in soft tissue, depending on the mobility of the tissues. Perlane lasts from 6 months to a year in the deeper plane of injection and along the bone, because there is little movement of the tissue.

EASE OF INJECTION Perlane is slightly more viscous than Restylane, but with practice it is really no more difficult to inject. It requires a deeper placement, but the volume used will be similar to that of Restylane.

TECHNICAL NUANCES Perlane can be used to correct deeper folds and hollows, and when used in combination with Restylane or Restylane Fine Lines/Touch, more detailed and precise correction can be achieved. It is important to remember to use the layering concept with these products to maximize their effect.

Combination With Other Fillers and Implants

As noted earlier, Perlane can be used safely and effectively to achieve excellent results over fixed implants or permanent fillers such as ArteFill. Restylane may be layered on top of the Perlane to maximally reduce the appearance of a fold. If the fold has a superficial line etched into it, Restylane Fine Lines/Touch is placed at the dermal-epidermal junction.

Postinjection Care

See postinjection information for Restylane.

Adverse Effects, Reactions, and Complications

Complications and adverse effects are similar to those for Restylane. If too much Perlane is placed in one area, it may become mobile (like a marble) in the deep layer. If this occurs, the material may be massaged down or removed through a puncture with an 18-gauge needle.

Results

This 48-year-old woman had periorbital hollowing as well as prominent periorbital fat in the central and medial aspects of her lower lids. She described this as her “polar bear” appearance and sought a more normal look and contour in her orbital and midface areas. A nonsurgical eye lift was planned as well as a midface augmentation. The malar bone was augmented with Perlane to increase malar projection and camouflage the prominent lower lid. Perlane was placed at the depth of the periorbital hollow on the bone and was also placed on the malar bone to augment cheek projection and minimize negative vectors. A total volume of 1.1 cc was placed per side, mainly in the periorbital hollow (1), but a smaller amount was placed on the malar bone to increase malar projection relative to the globe (2). The patient is seen 6 months after treatment. She is pleased with the improvement around her eyes and the increased projection and contouring in the midface.

Restylane Fine Lines/Touch

Indications and Applications

Restylane Fine Lines/Touch is the smaller cousin of Restylane and is comparable to Juvéderm 18. Although it is available in Canada, it has not yet received FDA approval. It is excellent for filling of the vertical lines of the lips as well as the fine lines of the glabellar region. It can also be used for superficial dermal lines that occur on the cheeks and for small soft scars, as seen on the left.

INJECTION TECHNIQUE AND LEVEL OF PLACEMENT

Restylane Fine Lines/Touch is placed at a very superficial level of the dermis or the dermal-epidermal junction with a 31-gauge needle with a very fine tip (supplied with a 30-gauge needle in Canada). The needle is placed just beneath the skin surface, and the material is injected to raise the bleb; this is then massaged smooth. The application is done along the length of the visible line. If needed, the material may be injected at the same depth along the length of the line in a linear fashion. The skin may appear blanched at the local site of injection initially, but this resolves within 5 to 15 minutes, unless local anesthetic with epinephrine has been injected. If there is any

concern about local skin ischemia, nitropaste 2% should be applied (a small amount only). In a patient with a great deal of sun damage, superficial placement may lead to long-term residual lumps or bumps (9 months to more than a year). These may be improved with massage, ultrasound treatment, and the application of hyaluronidase. Crow's-feet may be treated, but very fine lines should be approached with caution because of the potential for long-term bumps and possible bruising.

VOLUMES The volume of Restylane Fine Lines/Touch needed will vary, depending on the areas and depth of the lines. In general, for forehead lines 0.5 to 1.0 cc is used. For the fine marionette lines 0.2 cc is recommended. Care should be taken when this is placed in the vertical lip lines; if too much product is placed, it may make the lip appear stiff.

LONGEVITY This product will last 3 to 4 months, depending on the region, and 5 to 6 months in less mobile areas. Permanent scar correction can be obtained with Restylane Fine Lines/Touch, depending on the size and shape of the scar.

EASE OF INJECTION Restylane Fine Lines/Touch is very easy to inject, and care must be taken not to inject too much in the area of treatment. It generally takes less than 0.05 cc of material per placement of the needle. If the skin is thick and has multiple pores, injection may be more difficult, with small amounts of the product leaking into pores. If excess Restylane Fine Lines/Touch is injected, this can be corrected quite easily with massage.

TECHNICAL NUANCES Care must be exercised in patients with very thin skin, because superficial injections can result in long-term scarring that may not resolve. Another caveat is to avoid injecting Restylane Fine Lines/Touch in areas that are anatomically thin (the lower eyelid skin and lateral rhytids caused by the orbicularis oculi muscle). A topical anesthetic may be used, but this and local anesthetic can cause distortion (swelling) of the skin; therefore the line must be marked.

Combined Treatment

In the glabellar region, lines can be softened or eliminated for 8 months to a year when Restylane Fine Lines/Touch is injected in combination with *botulinum* toxin to limit corrugator function. Restylane may be needed to augment the deep layer of the dermis to attain maximal correction of the glabellar folds.

Postinjection Care

Postinjection bruising is less likely to occur than with Restylane Fine Lines/Touch, but treatment with cold packs and antihistamines is very helpful in reducing the recovery time.

Adverse Effects, Reactions, and Complications

Long-term scarring or bumps may occur rarely (0.1%) with very superficial injections. In our experience, in all cases to date, these have resolved almost completely, with the longest present for 1 year. As with any filler, good preinjection photographs are necessary, and documentation of other treatments (other fillers, laser, dermabrasion, and infections) will help to make the patient aware of preexisting deformities and improve long-term satisfaction for the patient and physician.

Results

Center: 1, This line lies over the dentition, and if too much filler is placed in this area, it will show as a bump.
2, A perioral line in this area is generally easier to correct than in position 1.

This 39-year-old woman presented with perioral lines that she wanted to improve or eliminate. Such lines are difficult to correct. Restylane Fine Lines/Touch is the best filler and must be placed very superficially. Postinjection taping with clear tape for the first 3 to 5 days can also help. It serves as a reminder to limit expression while the fibroblast and inflammatory response is taking place in order to prevent product migration. The patient is shown before treatment and 3 months after injection of 0.1 cc of Restylane Fine Lines/Touch. Note that the lines lie over the teeth, and if too much product is placed, it will give the mouth an odd appearance and may persist as a bump for a long time. Undermining of the line with an 18- or 20-gauge needle may help to soften it. This is done at a separate visit after the injection with a warning of possible bruising. This patient is very satisfied with the result and returns every 4 to 6 months for a touchup. Because of the repetitive movement of the fold, a permanent correction is very difficult to achieve.

Collagen

Features

The collagens include Zyderm and Zyplast, and CosmoDerm and CosmoPlast. Zyderm comes in two concentrations, 3.5% purified bovine collagen (Zyderm 1) or 6.5% purified bovine collagen (Zyderm 2). Similarly, there is CosmoDerm 1 (3.5% human fibroblast culture–derived collagen) and CosmoDerm 2 (6.5% human fibroblast culture–derived collagen). All collagens come premixed with 0.3% lidocaine, but lidocaine can be safely added to the latter. Two advantages of collagen over other injectable fillers are less pain with injection and less short-term swelling. So if a patient needs to attend an event the evening after an injection, short-longevity collagens would be an excellent choice of filler.

Indications and Applications

Zyderm and Zyplast are bovine collagen products; CosmoDerm and CosmoPlast are human collagen products. Although all products above are no longer available in Canada, they are still in use in the United States. Zyderm and Zyplast require two skin tests: the first test is followed 2 weeks later by a second test. Three to 4 weeks after the second test, if the patient does not have a reaction, the bovine product can be injected. Even with two negative skin tests, one in 1000 patients may still react to the bovine collagen injection. Skin reactions to bovine collagen can be debilitating. At their extreme, they can last for up to a year, with very little improvement with either topical or oral corticosteroids. For this reason many injectors are using bovine collagen only in patients who have previously had it and are requesting it. Zyplast is used in the mid-dermis in the nasolabial folds, melolabial and mental folds, angles of the mouth, vermilion border, and body of the lip to correct volume deficiency in these areas. Zyderm is used more superficially at the dermal-epidermal junction to correct fine lines. Zyderm would be used, for example, to correct the lines in the glabella that remain after a neurotoxin treatment. Additionally, Zyderm can be layered over Zyplast to give a more polished, longer-lasting effect than could be achieved with Zyplast alone.

Since the introduction of human collagen (CosmoDerm and CosmoPlast), it has become the choice of most injectors, because there is no risk of adverse allergic reactions. CosmoDerm is the equivalent product to Zyderm, and CosmoPlast is the equivalent product to Zyplast. CosmoPlast can be injected into the nasolabial folds to reduce the appearance of a valley between the nose and the mouth. Additionally, CosmoPlast can be injected into the vermilion border and the body of the lip to restore volume that the lips may have lost over time. CosmoPlast can also be used in the melolabial folds and mental folds to increase the volume and reverse the effects of aging in these areas. CosmoPlast may be injected into acne scars to correct them.

This effect can last up to 1 year. For the glabellar region, CosmoDerm and Zyderm would be used exclusively because of the risk of skin necrosis. Also, when attempting to correct the smile lines at the corners of the mouth, the injector should use CosmoPlast or Zyplast in the deep layer and would inject CosmoDerm or Zyderm more superficially over these lines to give maximal correction in an area in which typically a 50% correction is considered very good. These lines are difficult to correct because of the tissue pressure of folding created by smiling; we certainly do not want our patients to stop smiling to preserve the appearance of no lines.

VOLUMES All of the collagen products are supplied in 1 cc aliquots, and the volumes needed can vary from patient to patient. The lips may require a minimum of 1 cc and up to 3 cc, whereas the nasolabial folds may require 1 to 2 cc per side. Melolabial folds will require 1 to 3 cc total for correction. Usually 1 cc is more than enough to correct the mental fold, and often 0.5 cc is sufficient. Also, 1 cc is usually more than enough volume for all of a patient's acne scars. Adjustable needles are supplied to aid in injecting collagen to a precise depth, either to the mid-dermal region or at the dermal-epidermal junction.

LEVEL OF PLACEMENT CosmoDerm/Zyderm is placed at the most superficial level of the dermis (dermal-epidermal junction) with a 30-gauge needle; an overcorrection of 10% to 20% may be required. CosmoPlast/Zyplast, in comparison, is used for deeper folds and lines. This includes the nasolabial folds, marionette lines (melolabial folds), and mental folds. Injection to the glabellar area should be approached with caution because necrosis may result and has been reported with Zyplast, but has not been reported with CosmoPlast. This filler is placed at the mid- to deep reticular dermis, and care should be taken with the amounts injected so that lumps and bumps do not occur.

LONGEVITY CosmoDerm/Zyderm may last up to 4 months, with a shorter duration of 4 to 6 weeks on the lips. CosmoPlast will last from 4 weeks to 3 months.

EASE OF INJECTION Both Cosmoderm/Zyderm and CosmoPlast/Zyplast are relatively easy to inject compared with the hyaluronic acids, and with an experienced injector, good results can be achieved.

TECHNICAL NUANCES The human collagens are slightly easier to inject compared with the bovine collagens because the human collagens have an ease of flow that is probably unparalleled in comparison with any other filler. Additionally, both human and bovine collagen are prepackaged with lidocaine; as injection proceeds, the pa-

tient is more comfortable and experiences less pain. Massage is not a critical component of injection with collagen. Vigorous massage after collagen injection may actually result in decreased longevity; thus minimizing massage to the injected area is recommended. Unless the material has clearly resulted in a lump or bump, massage is not needed. Additionally, both collagens do not have much associated swelling and this is usually completely resolved within 24 hours in most cases. This added benefit translates into patients having injections in the morning and attending events in the evening. Technically the collagens are easier to use, although the correction achieved in patients with very deep folds may not rival the correction that can be achieved with the hyaluronans. For beginners, we suggest using the short-lasting collagens, perfecting their results, and then moving on to the hyaluronans, which have a steeper learning curve.

Combined Treatment

CosmoDerm/Zyderm is very useful in conjunction with Botox in the correction of vertical lines of the lips and for softening of crow's-feet and fine lines of the face and neck area. CosmoDerm may be used in combination with the hyaluronic acids to attain longer-lasting correction. There is little advantage in using CosmoDerm over Restylane Fine Lines/Touch. Both products have similar use and level of injection in the dermis. Restylane Fine Lines/Touch has much greater longevity than CosmoDerm and less chance of causing an inflammatory response.

Postinjection Care

Immediately after injection, if the patient takes 15 to 20 minutes to ice the face, very little swelling should result. If a bruise does develop as a result of the injection, it should resolve within 5 to 7 days. Provided that the patient does not ingest anticoagulants and anti-inflammatory agents before injection, the occurrence of bruising should be minimal and certainly less than that seen with the hyaluronans. Otherwise the patient should be able to carry on with the day's activities.

Adverse Effects, Reactions, and Problems

It must be noted that allergic reactions to the collagen products may occur. Skin testing is not required for CosmoDerm and CosmoPlast; however, patients receiving Zyderm and Zylast require at least one skin test. We perform two skin tests; the first test is at the first visit and the second is performed 2 weeks later. The second skin test is evaluated 4 weeks after it is placed. In evaluation, one is looking for redness, swelling, and plaques. Reactions can occur even if the test result is negative. It has been reported that a patient with two negative skin tests to bovine collagen can still have a 1:1000 chance of a reaction with subsequent injections. In our experience reactions to bovine collagen are rare but can be prolonged and incredibly difficult to

manage. Patients may experience redness, plaques, and scaling dermatitis that is unresponsive to application of topical steroids. The response to steroid injection is unpredictable, and sometimes patients are required to take oral prednisone for control of inflammatory responses. Scarring may be the end result. For this reason, we primarily inject CosmoPlast and CosmoDerm, the human collagen products, which have been shown to have low immunogenicity.

Repeated injection may result in scar formation in the soft tissues providing some longer-term permanent augmentation. With bovine collagen (Zyplast/Zyderm), inflammation was thought to contribute to long-term improvement. Human collagen (CosmoPlast/CosmoDerm) will not stimulate as much inflammation, because it is species compatible. In some patients, bovine collagen is not long lasting, and reactions still may occur. There have been reports of necrosis in the glabellar region when Zyplast was injected.

Radiesse

Features

Radiesse (BioForm Medical, Inc., San Mateo, CA) consists of 30% calcium hydroxylapatite (CaHA) and microspheres surrounded by a carboxymethylcellulose gel carrier. The technology is similar to that of ArteFill, but there are some differences. Radiesse is a little more biocompatible, because calcium hydroxylapatite is the same mineral component found in bones and teeth. This is a synthetic product, and the aqueous carrier gel is composed of glycerin and sodium carboxymethylcellulose and constitutes 70% of this product's volume. The carrier gel is replaced with the patient's own connective tissue 3 to 6 months after injection. Therefore no sensitivity testing is required. The carrier gel makes it a little bit thicker and a little more cohesive.

Indications and Application

Radiesse has been injected into the lips (not recommended), nasolabial folds, glabellar region, marionette grooves, and the mental fold. It has been approved by the FDA for the treatment of nasolabial/labiomental folds, HIV lipoatrophy, vocal cord insufficiency, radiographic marking, and facial skeletal reconstruction. It is also particularly appropriate for treating glabellar lines, acne scars, posttraumatic/poststeroid atrophy, and achieving cheek/chin/mandibular augmentation, and correction of nasal depressions or nasal augmentation. Injection of this product in the lips or superficial rhytids should be avoided, because doing so results in high rates of visible nodularity (20%). CaHA can also be used in hand rejuvenation.

Preoperative and 6-month postoperative results are shown after injection of 1.3 cc of Radiesse to the left hand in a 60-year-old woman.

Level of Placement and Injection Technique

Radiesse is supplied in 1 cc syringes. The placement is at the deep dermal level similar to ArteFill. The technique for injection and the planning for volume and line correction are much different than with the other fillers. The material is placed as the needle is withdrawn in a linear injection technique. Layering of the product at the deep level may help for areas such as the nasolabial folds. Cutaneous subcision will aid for very deep lines. Postinjection massage should be carried out to attain proper soft tissue contouring.

Similar to ArteFill small amounts of Radiesse must be placed with care to avoid irregularities, lumps, and bumps. Unlike with ArteFill most of the correction is achieved from the calcium hydroxylapatite particles within the product rather than tissue ingrowth around the particle matrix.

Volumes

This product is available in 0.3, 1.3, and 1.5 cc syringes and does not require reconstitution, as Sculptra does. Since it does not contain anesthetic, lidocaine 1% can be added at varying volumes, depending on the desired viscosity (this is an off-label use). Usually, in areas that require structural support, such as the cheek, 0.1 to 0.5 ml of lidocaine is used, whereas in areas of thinner skin, such as the tear trough, 1.0 ml of lidocaine is preferable. A 27- or 28-gauge needle can be used without clogging problems. The volume placed is similar to that of other fillers. Initially the injector should be conservative, because the material is long lasting; a relatively small volume provides a little larger correction than some of the other products. Approximately 1 cc of this product is comparable to the corrections that can be attained with 3 cc of Zyplast. The volume of augmentation is maximal at 4 to 6 weeks. Care must be taken with the amount of filler placed and that it is placed very evenly. For hand rejuvenation the recommended injection volume is 0.7 to 1.0 cc injected in small boluses subcutaneously and massaged to provide an even distribution. Lidocaine 1% 1 ml can be mixed with each 1 cc of CaHA injected to provide anesthesia.

Longevity

Radiesse has less long-term clinical follow-up in the soft tissues of the face compared with ArteFill and the hyaluronic acids, since its original indication was for use as a radiologic marker. It has a reported longevity in soft tissue of 1 to 5 years and in some reports up to 7 years, but the declared persistence is 1 year. An incidence of lump or bump of 8% to 10% has been reported by experienced injectors for contouring of the lips.

Ease of Injection

Radiesse has a higher viscosity and requires a larger needle size; however, the manufacturer supplies a special 28-gauge needle that facilitates injection, making it similar to that for hyaluronic acid fillers; injection is even easier if lidocaine is added. Injectors should start with the easier areas of correction, such as the nasolabial folds.

Technical Nuances

Care should be taken with injections, because the incidence of irregularity is higher than that of other fillers in the hands of new injectors. Deep dermal placement is important, since superficial placement may cause local irritation, bumps or rare granuloma formation. Furthermore, small-volume injection (less than 0.1 cc) and a uniform injection technique may help to prevent granuloma formation. After injection, massage will help to create a uniform contour; the product is pastelike and can be manipulated for several days following the injection.

Combined Treatments

Radiesse may be layered with other nonpermanent fillers. Taking preinjection photographs is as important for all patients having tissue filler injections as for patients undergoing cosmetic surgery.

Postinjection Care

Lumps, bumps, or irregularities may be treated by injecting them with dilute triamcinolone (Kenalog) on a monthly basis until they have resolved. Avoidance of blood-thinning medications and supplements before injection and topical icing for the first 24 hours after injection are also important.

Adverse Effects, Reactions, and Problems

Complications occur most often in the lips where there can be a 10% to 20% early nodularity rate. If a lump, bump, or irregularity occurs, it may be treated with a dilute steroid injection and massage. However, irregularities may require excision if they persist and do not respond to steroids. It has been found that when the volume injected into the lips is adjusted to 0.6 cc in the upper lip and 0.4 cc in the lower lip, the rate of nodularity decreases to half, or approximately 5%. *Radiesse is radiopaque, so patients should be informed of this to avoid surprises during routine dental x-ray examination.* The volumes required with Radiesse are similar to or somewhat less than those needed with other fillers.

Results

Preoperative

6 months postoperatively

15 months postoperatively

Courtesy Miles Graivier, MD

Preoperative and 6-month postoperative results after lip augmentation with 1 cc of Radiesse are shown. At 15 months the patient exhibits only a small amount of volume loss.

Courtesy Miles Graivier, MD

This woman underwent injections of 1.4 cc of Radiesse to her radiating lip lines, nasolabial folds, and white roll. The close-up view (*lower right*) clearly shows her more youthful appearance.

Sculptra

Characteristics

Sculptra (Sanofi-Aventis, Bridgewater, NJ) is an injectable filler composed of a suspension of poly-L-lactic acid (PLLA) microparticles (40 to 63 μm). This is the same type of material used in absorbable sutures such as Vicryl, or absorbable plates. It is a biocompatible and biodegradable polymer that breaks down, eliciting an inflammatory reaction, which contributes to collagenogenesis and fibrous tissue formation. Soft tissue augmentation is accomplished initially by the direct deposition of PLLA particles as well as the diluent. PLLA particles are suspended in carboxy-cellulose, mannitol, and normal saline solution. Once the diluent is absorbed, the volume-enhancing effect is partially lost; the PLLA particles remain to undergo a much slower degradation that takes place over a year. Macrophages break these particles down to lactic acid, water, and carbon dioxide, and the inflammatory process attracts fibroblasts, which in turn result in particle encapsulation and increased collagen tissue deposition. Therefore the final effect is somewhat delayed (weeks to months); that delay should be kept in mind while injecting Sculptra. As a result, multiple conservative sessions may be required. The longevity of PLLA can range from 1.5 to 2.5 years; however, additional injections may be required once the desired result starts to diminish.

Indications and Applications

PLLA has been successfully used in more than 30 countries under the name of New-Fill for a variety of facial volume and contour deficiencies including facial aging. In the United States, Sculptra is approved for the treatment of facial lipoatrophy seen with antiretroviral therapy in HIV-positive patients, and it recently received FDA approval for cosmetic use (Sculptra Aesthetic, approved July 2009). It is indicated for the correction of shallow to deep wrinkles, such as the nasolabial folds and marionette grooves, as well as contour deformities. Injection should be either in the deep subcutaneous planes or deep dermal layer or on the skeleton (forehead, malar region, jawline, and the base of the nose), avoiding more superficial deposition. The use of PLLA in superficial rhytids and the lips is contraindicated, because it can easily lead to visible and palpable inflammatory nodules.

Preoperative and 1-year postoperative results are shown after augmentation to the brow, cheeks and jawline with three sessions of Sculptra (2 vials per session) in a 51-year-old woman. The dilution of each vial of Sculptra consisted of 7 ml of sterile water and 3 ml of 1% lidocaine with epinephrine.

Product Preparation

Sculptra is a crystalline, amorphous, freeze-dried mixture with a 2-year shelf life in the unconstituted form. Dry PLLA is reconstituted with sterile water. The volume is 5 cc on average, but volumes as low as 3 cc (not recommended) and up to 20 cc have been reported, usually depending on the location being injected. Unlike other fillers, this product requires preparation by reconstitution at least 2 hours before injection. Some physicians prefer reconstitution 12 to 24 hours before injection. Once the water has been added, the vial is allowed to stand without shaking or agitation for at least 2 hours. The reconstituted suspension is stable for up to 72 hours and does not require refrigeration. After the 2 hours and immediately before injection, the vial must be agitated or rolled to ensure a uniform, translucent suspension. Although the manufacturer recommends discarding any unused product after 72 hours, there are reports of PLLA use 30 days after it has been reconstituted and kept at room temperature. Lidocaine 1% or 2% (1 ml), with or without epinephrine, can be added when preparing Sculptra to decrease the discomfort associated with injection. Injection is carried in the deeper layers first, usually by a depot technique. Then a more superficial layer is injected to provide a more “polished” volume augmentation. Postinjection massage is necessary to prevent nodule formation and optimize the outcome. Sculptra, a synthetic, is not derived from animal or human tissue; therefore it is not very immunogenic, and skin testing is not required.

Injection Technique

There are two basic injection techniques: tunneling and depot. The tunneling technique for deep dermal and subdermal injection is most suited for the lower face, cheeks, and nasolabial folds. The depot technique is for deeper placement of the product directly over the periosteum, such as the periorbital area and rim zygoma.

Tunneling Technique

For the tunneling technique, used for placement of the product in the deep dermis or subcutaneous tissues, the needle is placed at the appropriate level and the Sculptra is deposited as the needle is withdrawn, leaving 0.1 to 0.2 cc per injection or needle pass. In the cheeks, 20 such passes may be needed for contour correction.

Depot Technique

The depot technique allows product placement deep into the tissues just above the periosteum. The needle is guided through the tissues to the periosteum of the underlying bone, and then a depot of 0.05 cc is deposited. This should produce a visible and palpable elevation of the area.

In the depot technique, the area should be massaged to spread the product evenly over the bone, and then a second injection is performed. This is the technique for zygomatic enhancement and periorbital correction over the orbital rim deep to the orbicularis muscle. (Caution must be exercised in this area, because if nodules occur, they can persist for a long time.)

Volumes

The volume of injection will vary from individual to individual and area to area. Typically, for the nasolabial folds, volumes of 1 to 2 cc per side may be required. For correction of lipoatrophy of the cheeks and temple area, several milliliters per side may be needed and, in fact, multiple injection sessions may be required.

Longevity

Sculptra is a relatively long-lasting soft tissue filler. There have been reports of persistence of the product and volume correction up to 2.5 years in patients who suffer from lipoatrophy of the face.

Ease of Injection

The ease of injection depends on the consistency of the reconstituted product, which depends on the dilution with 5 to 10 ml of sterile water. Sculptra requires a 26-gauge needle or larger. Unlike most other fillers, it cannot be injected through a 30-gauge needle. If difficulty is encountered with the 26-gauge needle, a larger-gauge needle such as a No. 25 or 23 (rarely) should be used.

Technical Nuances and Tunneling Techniques

First, the entire area to be injected is marked; then the skin is stretched opposite to the direction of injection to facilitate skin penetration. The syringe plunger is drawn back to ensure that a blood vessel has not been entered, and then a thin trail of Sculptra is injected as the needle is withdrawn, no more than 0.1 to 0.2 cc per tunnel. This injection will produce a visible and palpable skin elevation in the area of injection. The injected area is massaged, and then another injection is made next to the previous one. Multiple injections in a crisscross pattern produce the best results. In patients requiring large volumes, it is best not to do the entire volume correction at one time. The injections can be repeated during a second session a week or two later. It is important not to overcorrect and to massage the area to distribute the Sculptra evenly.

Combination Treatments

Because Sculptra is designed for deep dermal or subcutaneous use, it is not a suitable product for correction of perioral, periorbital, and facial lines requiring deposition of a product more superficially. Deep treatment with Sculptra could be combined with the more superficial treatment with other suitable products.

Postinjection Care

Immediately after the completion of the injection, moisturizer is applied to the area and at least 5 minutes of massage is performed by the physician. Ice packs are then applied to the area to minimize bruising. The patient is also instructed to massage his or her face daily at home. The patient should be advised that much of the initial injected volume will be lost within the first weeks as water and postinjection edema are absorbed, leaving the microparticles of PLLA within or under the skin; that the full effect of the treatment may take a few weeks or months to be visible; and that a number of treatment sessions may be needed, depending on the severity of volume loss.

Adverse Effects, Reactions, and Complications

As with most injectables, bruising, swelling, and inflammation can develop after injection with Sculptra. More specifically, inflammatory nodules or papules can develop and are usually associated with injection at the superficial dermal/epidermal layers or injection in the lips. Skin discoloration can accompany such superficial nodules. The role of massage is critical in preventing such inflammatory nodule formation. Some data suggest that certain conditions, such as connective tissue disease or sarcoidosis, may predispose to a more pronounced inflammatory reaction (extensive granuloma formation and facial edema) with Sculptra injection.

ArteFill

Features

ArteFill (Artecoll in Europe and previously in Canada) has been used extensively in Europe and Canada for many years for soft tissue augmentation. It is comprised of collagen-covered PMMA beads, which are 40 microns in size. The particles of PMMA are noncharged and therefore they are found to have minimal (if any) reactivity in the tissue. They constitute 20% of the filler, while the bovine collagen component constitutes the rest 80%. The collagen is the transport vehicle for the PMMA beads and is absorbed over a 4- to 6-week period (or sooner), and the volume of the tissue is increased by the body making connective tissue around the PMMA beads in that time period.

Indications and Applications

ArteFill can be used in several areas. The safest indicated areas are the nasolabial folds and deep marionette lines. It is highly effective for deep soft acne scars and produces excellent long-term results for these types of scars. ArteFill has been used extensively in augmentation of the lips; however, there are reported incidences of irregularities, lumps, and bumps. Patients must be informed of adverse effects before receiving injections in the lips.

ArteFill has been injected into rhytids in the glabellar and periorbital region. The tissue in these regions tends to thin with age, and permanent fillers such as ArteFill may become visible over time. Correction of very superficial rhytids is difficult with ArteFill, and this is not an indication. Patients with a known allergy to collagen should be approached with extreme care with pre-injection testing with collagen for possible sensitivity. ArteFill has been used in patients of all ages and can result in excellent correction of deformity and scar in addition to providing great soft tissue augmentation results. It should be considered as one of the fillers of choice for permanent soft tissue augmentation.

Injection Technique

ArteFill has been injected in all of the soft tissues of the face as well as other parts of the body. It is injected in similar fashion to other soft tissue fillers. The recommended needle is 26-gauge, and it is supplied in a 0.5 cc syringe. ArteFill is placed as the needle inserted into the deep dermal plane is withdrawn. Once the ArteFill has been placed in a region, it must be massaged to make sure that there is uniformity of placement and that there are no lumps or bumps. Immediately after injection, mobile areas (nasolabial folds and lips) should have tape placed over them to limit the amount of movement and facilitate the formation of scar tissue around the beads. Tapes should be in place for the first 4 to 5 days. With lip augmentation, Botox should be injected around the lips in small doses (1 to 2 units in four points above and below the lips) in addition to taping the treated areas to prevent too much motion.

The technique for acne scars involves placing the ArteFill on the deep dermal plane with either simultaneous or subsequent release of the scar if necessary. As in other soft tissues, serial injections every 8 weeks may be required for complete correction of the scar. The material should be stored at 4° C and warmed to room temperature before use.

Level of Placement and Volumes

ArteFill is placed in the deep dermal plane. A nerve block is generally required for its administration. Initially, the average volume of ArteFill used in the lips is 0.5 cc per lip with patient follow-up 6 to 8 weeks after the injection. Varying amounts

can be used in other areas; nasolabial folds may require anywhere from 0.5 to 1.5 cc of ArteFill per side for correction. It is important to note that with initial injection the aim is to undercorrect the area.

Longevity

ArteFill is considered a permanent filling substance. As the patient ages, more volume may be required after about 1½ years.

Ease of Injection

Technically, Artecoll is the most difficult filler to inject. It is more viscous than any other filler and the syringes can contain air (due to the evaporation of collagen), which may cause irregularity in pressure and delivery.

Combined Treatments

Other fillers such as Restylane may be used in the same areas as ArteFill. A nonpermanent filler is often placed first; then a permanent augmentation with ArteFill is done 4 to 6 months later. Botox is very useful to help reduce the movement in areas such as the lips and glabellar region. The Botox treatment should be done 2 weeks before the ArteFill treatment to reduce the movement of the tissues in the first 3 to 5 days after the injection. Restylane Fine Lines/Touch should be used for the superficial lines rather than ArteFill. Care should be taken in patients undergoing treatments with radiofrequency as Artecoll may cause the tissues locally to receive more energy if the probe is placed right over the ArteFill. The PMMA is stable when subjected to very high temperatures.

Postinjection Care

The patient should be scheduled for a postoperative visit 6 to 8 weeks after the initial injection. They should also be informed that they will not see initial results for the first 6 to 8 weeks. In comparison to other fillers, there is only a mild to moderate increase in soft tissue augmentation in the first weeks as three fourths of the volume of the syringe is collagen, which is rapidly absorbed after the initial injection. Collagen is the vehicle for placement of the bead. Volume change occurs when the tissue grows into the bead. Cool packs and medications recommended for Restylane (such as antihistamines) will also help with reduction of postinjection morbidity.

Adverse Effects, Reactions, and Complications

One of the disadvantages of ArteFill is that irregularity will result if too much material is placed in one spot. If this is discovered soon after injection, it should be treated with massage followed by injection with a dilute dose of steroid (0.2 mg/ml

triamcinolone [Kenalog]) to soften the irregularity. Subsequent excision of the irregularity may be required if there is a persistent lump or bump. The incidence of granuloma formation is very low when ArteFill is injected with proper technique. It is highly recommended that a new user undergo supervised training before injecting ArteFill. With careful planning and placement of ArteFill, one can achieve excellent results for long-term to permanent soft tissue contouring.

Results

1, ArteFill is placed at the vermilion border first. 2, Augmentation of the dry lip must be done with care. 3, Augmentation of the wet-dry junction and the lateral lip (this can be turned out by injecting from the vermilion to the wet-dry mucosal junction).

This 33-year-old woman requested lip augmentation. She had a good lip shape to start with and was the ideal candidate for lip augmentation with ArteFill or any other filler. The injection was done under a nerve block with local anesthetic with adrenaline. ArteFill 1 cc was injected into the upper lip; 1 cc was also injected into the lower lip. It was placed in the vermilion border to increase border definition, projection, and size; the dry lip to increase size and projection; and the wet-dry junction to increase size and projection. She is shown 1 year after injection. No lumps, bumps, or irregularities are evident. The patient is very satisfied with the result and shows good long-term results and normal appearance of the lips when animating. The injections were done in two steps with 0.5 cc per lip per session 2 months apart. With ArteFill the injections should be planned 1½ to 2 months apart to allow maximal change with tissue formation around the beads. For the lips some patients may require a total of 3 to 4 cc. Patients with thin lips should be warned of the minimal to moderate change in size and shape. If too much volume is placed, there is an increased chance of lumps, bumps, or irregularities.

Center: 1, Areas where ArteFill has been placed in the deep dermis. 2, Areas where ArteFill has been placed in the deep dermis, and Restylane Fine Lines/Touch has been placed at the dermal-epidermal junction.

A total of 1.5 cc of ArteFill (0.75 cc per side) was placed in this 38-year-old woman, who requested amelioration of nasolabial folds and marionette lines. ArteFill was injected into the deep dermis of her nasolabial folds, lip-vermilion border, and marionette lines. Restylane Fine Lines/Touch was placed at the dermal-epidermal junction, overlying the area in which ArteFill was placed in the marionette grooves (a total of 0.4 cc: 0.2 cc per side).

This 47-year-old man demonstrates the effectiveness of ArteFill for correction of cystic acne scarring (*arrows* indicate acne scars). A total of 3 cc of ArteFill was injected into the deep dermis on each side of his face. Two sessions of injections were performed under local anesthetic 2 months apart to achieve the desired result. He also had 0.7 cc of Restylane injected into his upper and lower lip vermilion.

Autologous Fat Grafting

Features and Applications

The relatively recent development of effective methods of structural fat grafting have been revolutionary in contouring the face and body. Autologous fat enhances the subcutaneous volume and intramuscular size but does not act as a dermal filler. Basic indications are facial (cheek, malar hollow, jawline shape, chin projection, supra-orbital hollow, nose shaping), body contouring (buttock augmentation, correction of liposuction deformity, chest contouring, correction of scars), and more recently, the breast. With respect to the breast, fat grafting is very promising for primary augmentation, secondary corrections, and breast reconstruction, yet its use remains controversial. Proper training is required, and a long learning curve can be expected to achieve top-quality results.

In this 48-year-old man (*left*), fat was placed at 1, the deepest level of the infraorbital hollow, just below the orbital rim. The inferior extent of fat placement is indicated at 2. The fat is first placed to the deep layer at the inferiormost aspect, then added stepwise superiorly to the orbital rim; 3 indicates the malar high point. In the 38-year-old woman (*right*), Restylane treatment and fat grafting were combined to good effect to fill the infraorbital hollow.

Preoperative and 1-year postoperative results after microfat grafting to the hand are shown in a 58-year-old woman.

Preoperative and 1-year postoperative results are shown after microfat grafting to the temples, cheeks, and jawline and bilateral upper blepharoplasty in a 50-year-old man.

Common areas in which fat is placed for effective correction are the infraorbital hollow, malar region, the angle of the mandible, anterior/posterior jawline, chin, nasolabial folds, and the supraorbital/temporal region (1 and 2). Indications may vary from facial aging to lipoatrophy to congenital aesthetic deformities. Structural fat grafting is also extremely effective in the periorbital region in combination with lower and upper lid blepharoplasty, as well as in facial rejuvenation in combination with a SMAS technique to fill the periorbital hollow. The supraorbital region, the nasolabial fold, the jawline anterior to the jowl, and the nasal base may be augmented with microfat grafting in combination with face lifting.

In comparison to the injectable soft tissue fillers, autologous fat is an excellent tool for deep soft tissue filling and augmentation. Fat grafting is also effective in scar subcision when the scars are soft and fat filling is carried out underneath. Fat is also used to contour deformities of the nose, after either traumatic or aesthetic surgery. In comparison to the injectable fillers, results are variable when fat is used to contour the lips and perioral region. Fat can be used for deep soft tissue augmentation when it

is injected below the periosteum of the malar bone in the upper one third of the nasolabial fold. Fat may have decreased longevity when placed in the subcutaneous layer to soften the nasolabial fold if the patient has a dynamic smile with compression of the fold.

1, Primary depth of hollow in which Perlane is first placed, on the bone. 2, Area augmented with Perlane to contour the malar region and correct the "polar bear" feature.

The use of Perlane on the deep layer of tissue can achieve similar results to fat grafting in certain areas of the face as can be seen in this woman whose periorbital hollows and malar bone were augmented with this filler.

Injection Technique

The basic technique for microfat grafting consists of the harvesting of fat from a donor site and transplantation to a recipient site where it acquires a new blood supply, which enables it to survive. Technically, small packets of fat are placed in individual spaces to increase the volume of the tissue. These small packets acquire a new blood supply through angiogenesis. The cells that are transplanted may increase or decrease in size depending on weight gain or weight loss. Fat survival is technique dependent, and some cases may require secondary injections that may be done at varying lengths of time after the initial surgery. Fat storage after harvesting, for further or late grafting, is controversial, because fat cells have been shown to lose viability when frozen.

The technique for harvesting may be done with either a Coleman 14-gauge harvesting cannula or a Lambros 3 mm cannula (Grams Medical, Costa Mesa, CA). Aspiration is done with a 10 or 20 cc syringe held at 1 to 2 cc negative pressures to minimize trauma to the fat. The site of harvesting has no consequence with regard to results and longevity. Fat may be harvested from any location where there is excess. The fat is then spun for 1 minute at 1500 rpm to separate the blood, oil, and local anesthetic. The remaining fat is then transferred into syringes for injection using a variety of techniques, depending on the region, density, and thickness of the tissues. A 1 cc syringe is used in the facial region, with less than 0.1 cc of fat being placed with each pass. Varying degrees of correction are carried out when placing the fat. The harvesting cannula may also be used for injection of the fat in truncal areas.

Volumes

The volumes of fat required vary. In general, 3 to 7 cc may be used per side in the periorbital region and 2 to 5 cc for the nasolabial fold, 1 to 3 cc for the anterior jawline, and 6 to 15 cc for the posterior jawline. The surgeon should harvest two to four times the volume required for transfer, depending on the site and harvest technique.

Longevity

If fat survives transfer, it becomes permanent. It gains or loses volume if there is an increase or decrease in total body fat. It is sensitive to direct trauma, including forceps injury, and it is also sensitive to injury with radiofrequency devices (Thermage, Inc., Hayward, CA). Radiofrequency devices should not be used in areas that have been grafted. If a physician is contemplating fat transfer in combination with radiofrequency, the radiofrequency treatment should be completed before the fat transfer; this may be done immediately before the grafting procedure.

Adverse Effects, Reactions, and Complications

Complications of fat transfer are similar to those of any other injection or surgical technique. Care should be taken to deposit small amounts (0.1 cc) per each injection pass in the face to avoid fat emboli to the eye or brain. Technique-related complications include placing the fat too superficially in the thin skin of the upper and lower eyelids. Care should be taken not to inject the fat into the intramuscular or direct subcutaneous layer between the muscle and the skin. Fat placed in these areas will manifest as an irregularity, either static or dynamic. To address this complication, the surgeon may remove fat either through a blepharoplasty incision or a direct incision followed by pinching the fat with forceps. Other rare complications include infection/abscess, chronic inflammation, change in skin texture (peau d'orange), and fat graft survival, either too much or too little.

Results

This 48-year-old man is shown 1 year after microfat grafting to the malar region combined with transconjunctival blepharoplasty and canthopexy. A total of 6 cc of fat was placed per side in the subperiosteal region on the periosteum to augment the malar soft tissues and eliminate the periorbital hollow. The eyelid was not incised. Postoperatively the nasojugal groove and periorbital hollow were eliminated, and good lid position is exhibited.

This 38-year-old woman complained of fullness below her lower eyelid. This fullness was due to the orbicularis oculi muscle (1). Microfat grafts (4 cc) were placed on the deep layer below and up to the edge of the muscle bulge (2). She required only one grafting session and no eyelid surgery. She is shown 1½ years after injection.

This 60-year-old woman underwent a face lift, open brow lift, upper blepharoplasty, and lower eyelid transconjunctival blepharoplasty. Left: 1 indicates the superolateral extent for fat grafting. A total of 4 cc of fat was injected to the malar bone and nasojugal groove to increase cheek projection (2). She is seen 1 year after microfat grafting.

This 36-year-old woman underwent microfat grafting to the malar region and nasojugal groove (1) to correct her tear trough and periorbital hollowing. The oil from the harvested fat was injected between the skin and the orbicularis oculi muscle (2) to induce inflammation and scar tissue, which lightens the color of the skin. She did not require a blepharoplasty incision. She is seen 1 year after fat grafting.

This 34-year-old woman underwent transconjunctival blepharoplasty, canthopexy, and malar fat grafting to improve facial contouring (1 indicates an old scar). The fat was used to increase cheek projection, augment the malar high point, and decrease the nasojugal groove and periorbital hollow (2). She is seen 1 year after treatment.

Technical Guidelines for Filler Combinations

To achieve optimal benefit, tissue fillers may be used in combination. In particular, the hyaluronic acids, which come in three different sizes, produce excellent results when used in combination. The larger-molecule fillers, Perlane, Puragen, and Juvéderm Ultra Plus, should be placed in the deep layer followed by the addition of Restylane, Hylaform, Juvéderm Ultra, Eleveess, or Prevelle Silk in a more superficial plane. This layering can be done in both the nasolabial folds and the lips depending on the depth and severity of rhytids. Restylane Fine Lines/Touch is an excellent choice to use on top of either Perlane or Restylane at the most superficial level, the dermal-epidermal junction. Quite often the depth of a fold is associated with a fine line at its very deepest portion. The Fine Lines products are able to soften this line. Additionally, Restylane Fine Lines/Touch is quite useful in combination with Restylane, Hylaform, Juvéderm Ultra, Prevelle, or Eleveess for the glabellar region in which the fold may have a degree of depth and breadth of 1 to 2 mm with a very fine line running down the central deep portion. Again, to avoid tissue necrosis, caution should be used when injecting in the glabellar region.

For the lips, combinations of fillers may include ArteFill combined with Restylane/Hylaform/Juvéderm Ultra/Elevess or Restylane Fine Lines/Touch to achieve long-term correction and enhancement as is seen in this patient (also seen on p. 377). Combining Perlane and Restylane Fine Lines/Touch can achieve very similar results after repeat injections over a longer period of time. In some cases the combination of the two fillers produces results that may last from 8 months to 1.5 years. In areas such as the hollowing anterior to the jawline and jowl, Pelane/Puragen/Juvéderm Ultra Plus can be placed on the bone to give a deep-layer enhancement followed by subcutaneous or intermediate dermal placement of Restylane/Hylaform/Prevelle Silk/Elevess/Juvéderm Ultra to complete the correction of the deformity at the anterior jawline.

The combining of the larger molecules of Perlane/Puragen/Juvéderm Ultra Plus along with Restylane Fine Lines/Touch is quite useful in the treatment of acne scarring whose acne scarring was significantly improved with this approach. ArteFill is also a great choice for filling acne scars for permanent results.

Some individuals prefer to combine Restylane injection in the deep layer of the lip with Zyderm/CosmoDerm for the superficial augmentation. These individuals would inject the Zyderm/CosmoDerm before Restylane/Hylaform/Juvéderm Ultra to take advantage of the lidocaine anesthetic effect.

Results

This 47-year-old woman requested restoration of her lips, chin fold, jowls, and nasolabial folds. Note the herpetic outbreak on her left upper lip. She underwent injections of 0.35 to 0.7 cc of Perlane/Restylane into her nasolabial folds and 0.2 cc of Restylane with 0.2 cc Restylane Fine Lines/Touch into her extended nasolabial folds. She also had 0.2 cc Restylane placed into her marionette lines. Her mental fold was treated with 0.3 cc of Perlane/Restylane and 0.3 cc Restylane Fine Lines/Touch. Then 0.35 to 0.7 cc Perlane was injected on bone or into deep dermis to correct her jowls. She is shown 4 months after injection.

General Considerations and Technical Pearls

Technical Nuances

All fillers result in dramatic improvements if used correctly and precisely. It is important to note that the results achieved with each filler are dependent on a learning curve, and some fillers are more forgiving than others. When learning to inject fillers, it may be easier to use the collagen fillers because their viscosity is low and placement into the tissue is done with relative ease. Additionally, these fillers do not last as long as the hyaluronic acids. There are special adjustable needles provided with the syringes that make injecting for novices even easier. Collagen is formulated with lidocaine so a patient is more comfortable as the injection process proceeds. Perlane/Juvéderm Ultra Plus/Puragen and Restylane/Juvéderm Ultra/Elevess/Prevelle Silk are less forgiving when injected improperly. These must be placed precisely at the level of the deep dermis and mid-dermis, respectively. The amounts placed on each pass should be limited to less than 0.1 cc so that no lumps or bumps are created. If an irregularity is noted, then this may be massaged gently to reduce its prominence. If a large amount of material is placed at one site, then a possible sterile abscess may occur resulting in loss of volume in the region along with inflammation and swelling.

ArteFill can be used as baseline filler for the nasolabial folds and lips. Subsequently injections can be performed with Perlane, Restylane, or Restylane Fine Lines/Touch with excellent results. It must be noted that ArteFill, despite its permanence in the tissue, provides correction of a deformity only for a period of 1½ to 2 years. Age-

related changes and atrophy may give rise to the need for additional soft tissue augmentation.

Of these fillers, ArteFill is the most difficult to inject. It is highly viscous and must be warmed to room temperature to allow ease of injection. If there is loss of the collagen suspension, there may be air present in the syringe, which can make the injection quite irregular. Careful massage of the tissue must be done after placement so that no lumps or bumps remain. The larger 26-gauge needle causes more tissue trauma and bruising compared with the smaller 27- to 31-gauge hyaluronic acid needles. Perlane and Restylane are easier to inject than ArteFill.

Perlane/Juvéderm Ultra Plus is injected with a 27-gauge needle, and Restylane/Juvéderm Ultra/Prevelle Silk/Eleveess is injected with a 30-gauge needle. They can be placed with precision. Fantastic results can be achieved with proper training and a good aesthetic eye. Restylane Fine Lines/Touch is less viscous than Perlane and Restylane. It is placed at a very superficial level and may be placed in a serial injection technique by spot placement or by linear threading at a very superficial level. If an irregularity is noted, then gentle massage of the tissue will correct the deformity. It is supplied with a 31-gauge needle and tissue trauma and bruising are minimal.

Sculptra can be used in conjunction with most fillers other than ArteFill. Generally it is more of a panfacial filler; to add volume to the whole face and improve the texture and quality of the skin. More focused contouring may be done with the hyaluronic acids, Radiesse, or the collagens. Radiesse can be used in a similar fashion to Sculptra (panfacial volume restoration), but it does not have the same longevity. A patient may decide that he or she wants an immediate change instead of waiting 3 to 4 months for the results of Sculptra to be evident. But some patients like the longevity of Sculptra (1½ to 2 years versus Radiesse's 1 year).

Adverse Effects, Reactions, and Complications

All of the fillers have possible adverse effects. Perlane, Restylane, and Restylane Fine Lines/Touch have an incidence of reaction of approximately 1 in 3000. Reactions may occur such as local erythema, swelling, and deformity, which may be undulating and recurrent. This is rarely seen. Other reactions to the hyaluronic acids may include frank allergy, cellulitis, sterile abscess, local noncellulitic erythema, and telangiectasia. If the patient has preexisting telangiectasia, this should be noted before injection. Additionally, the patient should be informed that there is a possible risk of telangiectasia formation and that preexisting telangiectasias may become more severe and require treatment after injection. Soft tissue necrosis and embolic phenomenon have been reported but are rare. The area most implicated is the glabella, rarely on injection with Restylane and more commonly with collagen. An algorithm for treatment of blanching postinjection that includes warm compresses, nitroglycerine, epinephrine, hyaluronidase, and heparin has been proposed to reverse or minimize such ischemic events.

ArteFill can result in local granulomatous reactions (as with any soft tissue filler). The instances reported to date in North America are low (0.02% to 1%). There have been more extensive reports of granulomas in Europe (perhaps because of the earlier generations of the product). These may present as localized bumps or nodules that are tender to the touch. On histologic examination of the tissue, giant cells and multinuclear giant cells are present in the nodules, with an accompanying inflammatory response. If the product is placed too superficially in the dermis, the resultant tissue formation may lead to a white coloring of the skin. This is similar to the bluish discoloration (Tyndall effect) that may occur with any of the hyaluronic acid fillers when placed in the superficial layer of the dermis. If ArteFill is not placed in small amounts with each pass, deformities may result that can be difficult to treat. These nodules may be treated with local excision, massage, or injection of dilute steroid (0.2 mg/ml of triamcinolone [Kenalog]). A stronger Kenalog concentration (up to 40 mg/ml) may be needed to control the inflammation. If granuloma occurs, treatment options include direct steroid injection, excision, systemic treatment with oral steroids, or a combination of these treatments depending on the severity of the granuloma.

Bovine collagen (Zyplast and Zyderm) has been associated with severe local or regional allergic reactions that can become chronic and difficult to treat. Again, if these reactions are unresponsive or minimally responsive to local steroid injection, they may require oral steroid treatment. Allergic reactions can result in long-term scarring. Localized infection may occur after injections. No such hypersensitivity reactions are seen with human-derived CosmoDerm/CosmoPlast.

The injection of all filling substances may result in a herpetic outbreak if the patient has a predisposition. It must be noted that patients with a previous history of herpes simplex outbreak should receive prophylactic treatment with an appropriate antiviral medication.

Concluding Thoughts

The ideal filler has not yet been defined or created. There are a large number of fillers available in the international market; however, there are fewer available for use in the United States and Canada. The ideal filler may not be a single product. At the present time, a combination of available fillers provides correction of soft tissue rhytids and soft tissue augmentation and enhancement, and in some cases a non-surgical lift. A truly permanent filler may not be desirable as the facial soft tissues change with age. For example, certain patients who received silicone many years ago have resultant permanent deformities that cannot be corrected because silicone cannot be removed from the tissue. For this reason we do not inject silicone. The com-

ponents of an ideal filler include excellent safety profile, biocompatibility, longevity, ease of use, reproducibility, ease of storage, affordable cost, ability to combine with other fillers, and stability to give the most ideal result. It is important for physicians to have proper training and to understand the injection techniques that apply to each category of fillers. With precision placement and a good eye for aesthetics, tremendous results can be achieved. The combination of injectable fillers with surgical and nonsurgical techniques including *botulinum* toxin will continue to evolve as cosmetic surgeons continue to develop an understanding of the aging face and what is required to reverse this process. In particular, surgeons have moved to using a combination of tissue adjustment and volume restoration. Companies are eager to bring new fillers to the market. Each new tissue filler will have to be evaluated for its best application, technique of injection, amount used for quantifiable effect, ease of use, ability to combine with other fillers, longevity, and possible adverse effects.

Clinical Caveats

Off-label use of synthetic materials is technically possible but does carry some risk. The plastic surgeon is vulnerable from a liability standpoint, and discretion should be used when using products in an off-label manner. The patient must be informed of off-label use.

When treating deep folds and tear troughs, it is important to undercorrect these deformities. This results in a more natural appearance and leaves room for further correction in the future if that is desirable. Overcorrection of these areas can result in visible abnormalities and stigmata of filler use, particularly when the patient shows animation.

Inexperienced injectors should always opt for rapidly resorbable fillers such as bovine collagen (if available) and hyaluronic acids. This allows for faster resolution of any technical errors that may occur. Alternatively, in the case of hyaluronic acid fillers, hyaluronidase can be used to dissolve the filler.

Often in cases in which a slight correction is required, the patient forgets his or her preoperative appearance. It is imperative to use photography and point out any asymmetries before treatment to establish the patient's expectations and for comparison after injection.

Complications of dermal fillers can be avoided by the use of proper technique (small aliquots, appropriate level and quantity of injection, undercorrection, and massaging with some fillers). This is especially important with the longer-lasting fillers.

Annotated Bibliography

Coleman SR. Structural Fat Grafting. St Louis: Quality Medical Publishing, 2004.

Fat grafting is rapidly becoming one of the most requested procedures for a new generation. It offers a valuable tool to address patient demands for less invasive cosmetic procedures that produce natural, long-lasting results. The author provides surgeons with the expert guidance needed to master this technique for a wide variety of applications, including facial and hand rejuvenation, adjustment of facial proportions, and correction of liposuction deformities.

Kinney BM, Hughes CE. Soft tissue fillers: an overview. *Aesthetic Surg J* 21:469-471, 2001.

The worldwide search for the ideal soft tissue filler material continues. We focus on the stringent safety and efficacy requirements for soft tissue fillers and provide an overview of the current natural and synthetic materials.

Nahai FN, McGrath M. Tissue Fillers. Roundtables in Plastic Surgery, vol 1, no 2. St Louis: Quality Medical Publishing, 2004.

In recent years a variety of products have been brought to market that possess many of the properties necessary for improving facial appearance. Almost all of these innovative materials are effective for restoring youthful contours and fortifying aging skin; however, many of them work only in defined sites and planes of the soft tissue layers of the face. Additionally, all of them have short-term and long-term adverse consequences with various levels of severity. In this monograph an assembled panel of experts collect and organize the marketing information and clinical reports, present the regulatory status, and discuss what new products are in the pipeline. They also discuss the characteristics of each filler and debate their efficacy and clinical applications in a spirited roundtable discussion. Numerous pretreatment and posttreatment cases are presented.

Saylan Z. Facial fillers and their complications. *Aesthet Surg J* 23:221-224, 2003.

A number of facial filler materials that have not yet been approved by the FDA for use in the United States have been employed by physicians in Europe for several years. Although these products have proved efficacious, some complications events have been associated with their injection or inappropriate application. Moreover, the long-term effects of injecting into the face materials that cannot be removed without surgical intervention is an issue that deserves serious consideration by both physicians and patients.

CHAPTER 13

Structural Fat Grafting: *Basics and Clinical Applications in the Hand, Face, and Nose*

SYDNEY R. COLEMAN

Autologous fat grafting is a technique that has grown in popularity in recent years with the increasing demand for injectable tissue fillers and with new discoveries concerning the regenerative capabilities of transplanted fat. Interest in fat grafting applications has grown exponentially as physicians have recognized fat's enormous potential for solving aesthetic and reconstructive problems. As one of the most biocompatible of soft tissue fillers, autologous fat has broad applications in aesthetic surgery. Placement by separating the parcels one from the other encourages longevity, promotes stability, and effectively integrates the fatty tissue into the host tissues so that they are minimally detectable. Fat grafted in this manner is a safe, long-lasting, and natural-appearing tissue filler. It is also an effective means of changing facial and nasal contours, revising scars, and rejuvenating the hands and face. This chapter focuses on the basic principles of structural fat grafting and the most common applications for rejuvenation of the hands, nose, lips, and nasolabial folds.

Evolution of Technique

Physicians have been experimenting with injections of substances to alter surface contours of the face since the nineteenth century. In 1899 Gersuny first reported the injection of paraffin to replace resected testicles. He later reported on the use of paraffin to correct facial contour deformities. Additional reports on the use of paraffin for correcting facial defects were later made by Miller and Kolle. As paraffin use fell into disfavor because of the many complications associated with it, aesthetic surgeons continued to use injection techniques with other substances such as rubber and purified latex in search of the ideal filler material. In 1908 Eugene Holländer of Berlin first published his experiences with injecting fat into the face. In 1912 Holländer published before-and-after photographs of the use of injectable fat for correction of facial atrophy and breast scarring. In 1926 Charles Conrad Miller in the United States described his experiences injecting fatty tissues through cannulas.

The introduction of liposuction in the 1980s helped to popularize this idea of using autologous fatty tissue for implantation. A byproduct of liposuction, the suctioned semiliquid fat could be reinjected through cannulas and needles. The ready availability of semiliquid fat after liposuction helped to renew surgeons' interest in grafting autologous fat through a cannula, and myriad techniques for grafting have been introduced since that time, with mixed results.

In 1987, after initial success with grafting fat into iatrogenic liposuction deformities, I began to place fat in the face for aesthetic reasons. These early efforts yielded long-term structural changes that have demonstrated permanence. Since that time the technique has been refined, altered, and improved to ensure better integration and stability of the grafted fat and to provide an alternative method, outside of traditional surgical techniques, for altering facial contours and contributing to overall facial rejuvenation. It has also been used successfully for hand rejuvenation and for treating iatrogenic deformities resulting from liposuction. (See Chapter 87 for more information on fat grafting for iatrogenic deformities.)

Pretreatment Assessment

Determining the specific amount of fat and the levels of placement necessary to execute subtle contour changes in the face requires a well-developed strategy. Before a plan can be established, the surgeon must evaluate the patient's appearance and acquire information on the patient's lifestyle, expectations, prior aesthetic procedures, and medical history.

The surgeon should carefully review past aesthetic procedures to make certain nothing has been overlooked. In my experience, injections of silicone and even fat are the procedures that patients most often neglect to mention. Even if patients disclaim any injections on the intake form, it is advisable to ask whether they have had silicone, collagen, or fat injections. Because the presence of scars on the skin can influence the approach for placement of fat grafts, the history should include skin biopsies, punch biopsies, and so forth.

Because structural fat grafting is invariably an elective procedure, the treatment of candidates in poor general health should be approached with caution. Problems with bleeding, bruising, and unusual swelling after prior procedures should be addressed to prepare the patient and surgeon for similar problems. A history of any outbreaks of fever blisters on the lips is solicited to determine whether herpes simplex prophylaxis is indicated. A neurologic history is essential. Fat infiltrated into the muscles of a patient who has recovered from a facial nerve injury or Bell's palsy may act as a stent, inhibiting movement in the affected areas of the face. Any history of psychiatric problems and their current status, along with their possible impact on the surgical patient, should be carefully considered before a patient is accepted.

I schedule several consultations with a patient before surgery. For patients interested in rejuvenation procedures, I ask them to bring photographs of themselves when they were young to help determine the degree of augmentation needed. These photographs provide a better gauge of the patients' aesthetic preferences. Patients need to understand the details of the planned procedure, the expected outcome and postoperative course, their responsibilities during recovery, and possible sequelae and complications.

Informed Consent

In my experience, the most important part of the informed consent process is the time spent with the patient in preparing for the procedure. In addition to a verbal explanation of the procedure and the perioperative course by the surgeon and nurses, the patient is given printed material for referral. It is important to prepare the patient for the postoperative swelling and bruising and the potential for complications. Although this procedure is associated with a high rate of long-term patient satisfaction, patients who are not prepared for the expected or unexpected postoperative sequelae can pose major problems.

Physical Examination

Physical examination of the face supplements the photographic documentation. Because photographs cannot capture the relationship of the underlying structures to the skin, palpation is used to determine landmark relationships, such as the height of the infraorbital rim compared with the eyelid and the relationship of the angle of the mandible to the actual shadow of the jawline.

Pretreatment Planning

Photographs

Detailed photographic documentation is essential to successful structural fat grafting. Photographs record the patient's preoperative appearance and serve as a basis for three-dimensional analysis. For example, in the face I take photographs of the patient from a variety of angles and views. In all of these views, the patient's hair should be pulled back from the face and ears, even for male patients, and collars should be pushed down or clothing covering the neck should be removed. At least one set of pretreatment photographs is taken with the patient wearing no makeup so that the color and texture of the skin can be documented.

Tracings and Blueprints

Summary of Perceived Problems

When grafting fat in the face, tracings of the patient's face are used to evaluate perceived problems and document patient complaints. They are used when I plan the procedure and in discussions with the patient. I use them to predict the volumes required, the level of placement, and the structural support required to achieve the desired changes. These tracings also serve as a form of informed consent to document the planned changes during the consultation, detailing areas of fatty tissue placement and removal as well as incision sites. What is most important, they serve as a reference for making the markings immediately before treatment and during the procedure.

On a separate tracing I summarize the operations over the facial features involved. I also ask patients to describe all *botulinum* toxins, hyaluronic acid, calcium hydroxylapatite, collagen, silicone, or other substances injected into their faces and map this information on the tracing, along with the time of these injections.

Markings

On the day of the procedure, colored marks are drawn on the patient's face using the blueprints created at the second consultation as guides. The markings outline areas to be augmented and amounts of tissue to be infiltrated. These markings also serve as reminders of the specific levels of placement against the skin, against bone, or in intermediate levels. I photograph these markings with a digital camera and print them out for a quick record; they are also stored at a higher resolution for a higher quality record. These digital images and printouts of the markings serve as a useful reference during the procedure, especially because the markings may become obliterated during placement of the fatty tissue.

If the patient later says, “Well, I didn’t really understand you were putting fat there. I thought you were going to put fat into my forehead also!” I can point to the documented markings on the photographs in that area to gently remind the patient of the original plan that he or she agreed to.

Harvesting, Refinement, and Transfer

The basic principles of structural fat grafting include the following:

1. Harvesting with a blunt cannula and syringe using low suction
2. Refinement with centrifugation to facilitate removal of nonliving components
3. Purposeful placement into recipient tissues, separating parcels from each other

Fatty tissue is more fragile than most other human tissues and is easily damaged outside the body by mechanical, barometric, and chemical insults. To survive harvesting, transport, and implantation with cannulas and syringes, fat must be harvested in intact parcels small enough to be inserted through a small cannula but large enough so that the tissue architecture is maintained.

Material harvested by syringe liposuction may contain as little as 10% or as much as 90% of fatty tissue on centrifugation. The aspirated material separates into three layers: the top layer is composed primarily of oil, the bottom layer is almost entirely made up of blood and lidocaine, and the middle layer contains potentially viable parcels of tissue. If each sample is composed of a different percentage of viable fat, it is very difficult to accurately estimate the volume for placement. To obtain consistent predictable results, most of the oil, blood, and lidocaine can be gently removed from the harvested tissue by sedimentation or centrifugation.

Preparation for Harvesting

Because I have observed no clear correlation between donor site location and longevity of the implanted tissues, I select harvesting sites that enhance body contour and provide maximal access to the patient in the supine position that is used for almost all facial augmentation procedures. The abdomen and medial thighs are commonly chosen donor sites. When abdominal or medial thigh fat is limited because of prior liposuction or low levels of body fat, the suprapubic region, the anterior thighs, and the area above the knees are the next choices.

When the patient is placed in the prone position, the posterior medial thighs, lateral thighs, and the love handles are prime options for donor tissue. In patients with low body fat, especially men, the abdomen and love handles may consist mostly of fibrous tissue with little available fat. Using the thighs as donor sites in these men is often a viable alternative.

Donor Site Access

Whenever possible, harvesting sites are accessed through incisions placed in creases, previous scars, stretch marks, or hirsute areas. The pubic region is the most useful incision site because the abdomen, medial thigh, and anterior thigh can be reached with ease. To harvest fat from the upper abdomen and flanks, additional incisions can be made in the umbilicus and upper abdomen. With the patient in the supine position, the knee can be reached through an anterior knee incision. Occasionally an incision in the lateral hip can also be used for access to the thigh or to the lower love handle. Incisions in the midback and lateral sacrum provide access to the love handles and flank.

Sterile Technique

Bacterial contamination of the fatty tissue can result in infection that causes re-sorption of the grafted material. Therefore meticulous sterile technique is always observed with careful attention to preoperative patient preparation.

A blunt Laminar infiltrator attached to a 10 cc syringe is used to infiltrate the lidocaine solution into the projected sites of fatty tissue removal. Usually 1 ml of lidocaine is infiltrated for every cubic centimeter of fat harvested.

Epidural or general anesthesia is preferred for removal of larger volumes or when multiple sites are used. To ensure hemostasis, Ringer's lactate in a concentration of 1:500,000 epinephrine is also infiltrated in a ratio of 1 ml of solution for each cubic centimeter of fat harvested using a blunt Laminar infiltrator. Tumescent techniques are not used during the harvesting phase.

Basic Harvesting Instruments

Instruments for structural fat grafting should be efficient and minimally traumatic to the grafted tissue during both the harvesting and placement phases. A two-hole cannula with a blunt tip and dull distal openings placed extremely close to the end is used for harvesting.

The distal openings of the harvesting cannula are the appropriate size and shape for harvesting the largest intact fatty tissue parcels that can readily pass through the lumen of the Luer-Lok syringe and will therefore also be able to pass through the much smaller (17-gauge) lumen of the infiltration cannulas without clogging.

The length of the harvesting cannula is usually 15 cm. Although a 23 cm cannula has a greater reach, it can potentially place greater torque on the Luer-Lok aperture and break the syringe tip during extraction. It is advisable to use the shorter cannulas initially, advancing to longer ones once the surgeon is more familiar with the instruments. After a surgeon becomes adept at using straight harvesting cannulas, then he or she should advance to the use of curved cannulas to follow the curvature of the flanks, thorax, or thighs. The curved cannula can be especially helpful when harvesting from the abdominal midline through an umbilical incision to keep the tip of the cannula from slipping into a deeper plane.

The incisions made for infiltration of anesthetic solutions are also used for harvesting fatty tissue. These incisions are just large enough (usually 2 to 3 mm) to permit insertion of the tip of the harvesting cannula. The inserted cannula is attached to a 10 cc Luer-Lok syringe by the Luer-Lok connection. Only 10 cc syringes are used for harvesting; these are small enough to be manipulated manually without locking devices.

During removal of fatty tissue, care is taken to minimize mechanical trauma to the fragile parcels of fat. The plunger of the syringe is gently manipulated to provide 1 or 2 cc of negative pressure space in the barrel of the syringe while the cannula is pushed through the harvest site. Initially excess fluid may be noted in the harvested material. When substantial fluid is present, the syringe is placed on a table for several minutes to allow the fatty tissue to separate from the liquid component. Then the aqueous portion can be expressed by pressing on the syringe. The syringe with the refined fat is then reconnected to the cannula, and harvesting continues until a greater quantity of fat has been obtained. All incision sites are closed with nylon interrupted sutures after harvesting is completed.

Refinement

After the fat has been harvested, the cannula is removed from the syringe and replaced with a dual-function Luer-Lok plug for capping; this is available in most hospitals.

Centrifugation

After the Luer-Lok syringe is sealed, the plunger is removed from the proximal end of the syringe. The syringe minus the plunger is then placed into a centrifuge to separate the viable from the nonviable components. The recommended centrifugation is 1300 G, which translates into 3000 rpm on the most commonly used small laboratory centrifuges. I have found the optimal centrifugation time to be 3 minutes. Each 10 cc syringe is placed in an individual sleeve of the central rotor of the centrifuge. These sleeves can be changed or emptied in case of spillage of the aqueous portion of the syringe. Care should be taken to choose 10 cc syringes that fit into the sleeves easily.

Centrifugation separates the denser components from the less dense components to create multiple layers. The upper level, or the less dense level, is composed primarily of oil; the middle portion is composed primarily of potentially viable parcels of tissue and the lowest level is the densest layer and is composed primarily of blood, water, and lidocaine. The middle portion has more oil present in the upper portion and denser tissue present in the lower portion. It has been my observation that the denser fatty tissue in the lower portion has a greater reparative effect on the tissues into which it is injected, and appears to have a more predictable survival. Studies are currently being conducted to verify these observations.

Separation of Components

To avoid losing the vacuum that holds the contents in place, the oil layer is decanted first, before the plug is removed from the Luer-Lok syringe. (The oil can be used for lubricating both the harvesting and insertion site incisions.) After the oil is poured out of the syringe, the plug is removed from the syringe and the aqueous portion flows out through the Luer-Lok aperture.

Wicking the superior portion of harvested fat using neuropads or Telfa strips removes more of the remaining oily component of harvested fat. After 4 minutes, the wick is replaced with another piece of wicking material. Wicking is performed at least twice. Fat may stick to the material as the wick is removed, but scraping the fat off the gauze can irreparably damage the fat. If the surgeon suspects that some of the fat has been damaged by excessive exposure to air or mechanical trauma, the fat should be discarded.

The plunger is then replaced after the fatty tissue is allowed to slide down to the edge of the syringe. A finger should be pressed over the Luer-Lok aperture to control the fat slippage with air pressure. The plunger is then placed into the syringe and ad-

vanced to obliterate the dead space. The fat can be stored in the 10 cc syringe in this fashion for brief periods of time before being transferred to smaller syringes for infiltration. Advancing the plunger of the 10 cc syringe with the Luer-Lok aperture placed at the base of the smaller syringe transfers the contents. Both syringes should be kept in a relatively vertical orientation to avoid accidental insertion of air bubbles into the column of fat during transfer. I use only 1 cc Luer-Lok syringes for placement of the tissue into the face and hands and 3 cc syringes for the body.

OVERVIEW: FAT REFINEMENT AND TRANSFER

Placement Techniques

Placement of the refined fat into the recipient site is the most challenging part of fat grafting. Fat parcels should be placed to ensure uniform survival, stability, and integration into the surrounding recipient tissue. The key to fatty tissue placement is maximization of the surface area of contact between the harvested fat and the recipient tissues. By placing these small parcels of fat so they are separated from each other by the host tissue, the larger surface area of contact can be maintained. Because bacterial contamination may destroy transplanted fat, scrupulous attention is paid to sterile technique.

Regional blocks using 1% lidocaine with 1:100,000 epinephrine through 25-gauge needles are used when appropriate and convenient. For all planned incision sites on the face or body, I place a solution of 0.5% lidocaine with 1:200,000 epinephrine with a 27-gauge needle. Incisions 1 to 2 mm long are made in the face, neck, body, and hands; these are also used for placement of the fatty tissue. Small amounts of the 0.5% lidocaine with 1:200,000 epinephrine are diffusely infiltrated using the structural fatty tissue cannulas into the areas of planned placement.

The infiltration cannula is inserted through each tiny incision that was used for infiltration of the local anesthesia and advanced through the tissues to the appropriate plane. The skin is stabilized with the opposite hand. No fatty tissue should be ejected during the advancement of the cannula into the recipient tissues.

Once the cannula is in the desired location, *the plunger of the 1 mm syringe is pressed slightly while the cannula is being withdrawn*. A small aliquot of fatty tissue is then left in the pathway of the retreating blunt cannula, permitting more stable and regulated placement and minimizing the potential for irregularities or clumps of tissue.

Placement of minuscule amounts of fatty tissue with each pass is critical to successful structural fat grafting. To maximize the surface area of contact, the largest amount of tissue that should be placed in the face with each withdrawal is $\frac{1}{10}$ cc. Intact parcels of fatty tissue should be somewhat separated by the tissues of the recipient site to maximize the surface area of contact between donor and recipient tissues.

Estimating the volume to be placed in each area can be challenging, and there is little room for error. Minimal compensation should be made for resorption in this situation. The injected material is not pure fat; even after refinement, there will be quantities of blood, lidocaine, or oil present in the refined fatty tissue. Therefore it is best to use small amounts of infiltrate initially, increasing the amount gradually as experience is gained. The use of 1 cc syringes initially is particularly important to prevent overzealous augmentation.

Use of Blunt Cannulas

Although I switched from sharp to blunt cannulas in 1992 to avoid injuries to underlying structures, I have also found blunt instruments to be superior for placing fatty tissue autografts in other regards as well. Unlike the sharp tip of a needle, the blunt tip does not cut a swath through the tissue. As the blunt tip is advanced, the natural tissue planes separate in a more physiologic fashion. As the blunt cannula is withdrawn, the deposited fatty tissue parcels fall into the natural tissue planes as the host tissues collapse around them. In addition, using blunt cannulas for more stable placement of fatty tissues allows the surgeon to place much larger volumes of fatty tissue. Finally, placement with a blunt cannula reduces the possibility of intravascular injection of the fat.

Stability of Transplanted Fat

Separating the parcels of fat does more than increase the chance of survival. Placing the fatty parcels with a blunt cannula that causes minimal disruption of the natural tissue planes facilitates better fat adherence to the recipient sites. Minimal destruction of the tissues and maximal surface area of contact combine to create a more stable relationship between the new fat parcels and the surrounding tissues.

After the edema resolves, the texture of the grafted tissues essentially resembles that of the host tissues rather than retaining the structural qualities of fatty tissue. By placing fat in small parcels and separating every parcel with the donor site tissues, the fat becomes integrated with and feels like the tissues into which it is placed.

This three-dimensional technique of placing refined fat into the recipient sites creates the shape, volume, and structural changes defined in the operative plan. Accuracy of the initial placement is imperative, because the infiltrated fatty tissue is difficult to remold afterward. The fatty tissue should be deposited in the desired location, shape, and volume with each pass of the infiltrating cannula. If a cyst or clump forms accidentally, digital manipulation can sometimes flatten such minor irregularities. However, *the tissue should never be placed with the idea that digital pressure can change the shape after placement.*

Structural Manipulation

The host tissues can be manipulated to change their shape better if the fatty tissue is placed bluntly in minuscule amounts with each pass. If the tissue adheres to the recipient tissue after each pass, then multiple passes can change the intrinsic shape of a site while adding volume. Injections in the nasolabial folds, lips, and lower eyelids to relieve scleral show are examples of structural manipulation.

Instrumentation for Placement

The instruments used for placement of fatty tissue are dramatically different from those used for harvesting; they are shorter and have a smaller gauge, with only one hole at the distal end. The fat infiltration cannulas vary in length and shape, but the most useful lengths are from 5 to 9 cm for use in facial procedures and from 9 to 15 cm for body-contouring procedures. Cannula tips also come in various sizes and shapes for individualized treatment.

To facilitate structural fat grafting, I have developed three different styles of blunt-tipped cannulas as well as a V-dissector, each with its own function. I developed these beginning in 1993 (Byron Medical, Tucson, AZ, a division of Mentor):

The Coleman style I cannula is completely capped on the tip, with a lip extending 180 degrees over the distal aperture. It is my workhorse, and its primary purpose is to minimize traumatic injury to underlying structures.

The Coleman style II cannula is similar to the style I but is not totally capped. It has a lip extending over the distal aperture approximately 130 to 150 degrees. This cannula is useful in most situations.

The Coleman style III cannula is flat on the end, permitting dissection of tissues in specific situations; for example, when pushing through scars or fibrous tissue. It is also helpful when placing tissue in immediately subdermal or submucosal tissue.

The Coleman V-dissector is used for release of adhesions.

To facilitate use in different areas of the face and body, the cannulas come not only in a variety of lengths but also in numerous sizes from 20 to 14 gauge. The smallest gauges are used in the periorbital region and the larger gauges can be used in the body.

As a result of recent concerns about the sterilization of small-bore cannulas, a line of high-quality disposable cannulas is now available in the same shapes and sizes.

SPECIFIC CLINICAL APPLICATIONS

Hand

The hands are one of the first areas to exhibit visible signs of aging. The simple, reliable technique of autologous structural fat grafting can be used to achieve long-lasting rejuvenation of the dorsum of the hand, restoring a slight fullness to atrophic subcutaneous tissue, softening the color, defining the exposed extensor tendons and veins, and supporting the aging skin.

The key to structural fat grafting of the dorsum of the hand is purposeful placement of a smooth layer of tissue against the undersurface of the dermis, with extra placement into deficient intermetacarpal and web spaces. The goal is to restore a youthful fullness to the back of the hand.

Aesthetic Considerations

The dorsum of an attractive, healthy-appearing hand has a slight subcutaneous fullness that obscures veins and tendons but does not hide them. The tendons are more defined when the metacarpophalangeal (MCP) joints of the wrist are extended than when they are flexed or in repose. The superficial veins are usually discernible, and the more slender and athletic a person is, the larger and more distinct these veins appear. The blue color of the veins can be seen through the skin, but the white tendon color is not usually discernible. There is a generalized fullness of the skin and subcutaneous tissues that adds volume to the nonbony hand and frames the joints with a youthful fullness.

In the dorsum of an aging hand, generalized subcutaneous fullness gradually disappears as the subcutaneous tissues atrophy. With loss of fullness, the veins appear more prominent, their blue color deepens, and the extensor tendons appear whiter and more visible through the thin skin of the dorsal hand. The tendons are promi-

ment even at rest or with flexion of the MCP joints. With the loss of supporting fullness under the dermis and a gradual diminution of elasticity, the skin's texture becomes more crêpey and wrinkled.

The intermetacarpal spaces deepen, especially between the thumb and the index finger, and there is some loss of intrinsic muscle volume. With loss of fullness in the hand, the fingers and joints may appear enlarged and arthritic.

Anatomic Considerations

Only the bluntest of cannulas, style I, is used at all times in the hand to avoid damaging underlying structures. With careful placement in the subdermal layer between the veins and skin, few anatomic structures are exposed to trauma. Even the trauma to the veins is so minimal with this technique that I have rarely seen significant bruising after structural fat grafting to the dorsum of the hand. The primary potential for anatomic problems results from manipulation of fat after placement. Strong digital pressure on a clump of fat can push the newly grafted tissue deep to the tendons or even deeper into the intrinsic muscles of the hand.

Indications and Patient Selection

Persons with noticeable loss of subcutaneous fullness of the dorsal hand and apparent thinning of the skin are the best candidates for hand rejuvenation with fat grafts. These patients usually also have prominent underlying veins and tendons along with an increase in the crêpiness of the skin. Patients with intermetacarpal wasting or arthritis are also candidates for this procedure because adjustment of the volume proportions of the hand will create a much healthier appearance by decreasing the relative size and boniness of the joints.

Technique

This 57-year-old woman is typical of patients seeking fat grafting for hand rejuvenation. She thought that her hands looked much older than her face, with gradual loss of the fullness that created a “bony” appearance. She especially disliked how her joints appeared enlarged and arthritic, even though she had no functional problems. The well-defined tendons glistening through her thin skin also bothered her, and she believed that her hands were much too “veiny.”

Markings

The patient's hands are marked with borders of placement delineated by the orange line running along the fingers and down the ulnar and radial hand, crossing the proximal forearm. Places where more tissue will be placed are marked in green, and larger veins are marked in blue.

Anesthesia

General anesthesia or heavy sedation and a double-level wrist block are most often used for anesthesia of the hands, as was done for this patient. The 1% lidocaine with 1:100,000 ml of epinephrine is placed superficially with 25-gauge needles at two levels: one just proximal to the planned area of infiltration and another approximately 2 cm proximal to the first block.

Incisions

Incisions are made with a No. 11 blade in the direction of the wrinkle lines, at six or seven sites spaced around the periphery of the hand. The incisions are a little longer than 1 mm.

The best locations for incision placement are the following (*see red circles*):

- Ulnar and radial wrist, at the level of the MCP joints at the ulnar little finger
- Central dorsal wrist
- Web space between the ring finger and middle finger
- Radial index finger
- Radial thumb

Infiltration Cannulas

To avoid damage to underlying structures, particularly the veins, a blunt 17-gauge cannula is used for fat placement in the hand. This blunt infiltration cannula is completely capped on the tip, with a lip that extends 180 degrees over a solitary distal aperture. I prefer cannulas that are 7 or 9 cm in length.

Level of Infiltration

The level of placement is almost entirely in the immediate subdermal plane superficial to the veins, where it can provide support to the skin.

Placement Volumes

I generally recommend placing at least 20 cc of fat in each hand. More fat will be required for patients who want significant feathering onto the forearm or correction of intermetacarpal wasting. Extreme overcorrection should be avoided; I place only as much tissue as is needed to achieve a specific result based on my previous experience.

The basic placement technique is the same as for any location on the face. With each pass of the cannula, less than $\frac{1}{10}$ cc and sometimes as little as $\frac{1}{50}$ cc is placed; $\frac{1}{10}$ cc is considered the maximum increment of tissue to place in the hands or face. The small 1 cc syringe provides much greater control over increments placed with each pass. Accuracy in the initial placement is crucial, because once placed, it is difficult to reliably change the shape of the fat significantly after placement, especially after edema is present. As the tissue is incrementally infiltrated with multiple passes of the cannula, a plane of fat is created by placing minuscule amounts of tissue in close proximity to each other, but separated by a tiny space. If the surgeon accidentally allows a lump or irregularity to form, immediate digital manipulation will usually flatten it to ensure that the newly placed fat looks and feels smooth to the touch.

Sequence of Placement

I start with the phalanges and proceed proximally over the web spaces, dorsum of the hand, and dorsum of the wrist and forearm, if indicated. Placement is almost all immediately subdermal, with occasional slightly deeper placement in deep intermetacarpal deficiencies.

The proximal phalanges and web spaces are usually approached first. Placement usually begins with the radial MCP thumb incision into the proximal phalanx of the thumb. This placement is sometimes difficult because of the adherent nature of the skin over the thumb MCP joint, so the incision should not be placed on the volar surface of the thumb, but more in a more dorsal direction.

Next, the proximal phalanx of the thumb is infiltrated from the ulnar incision at the level of the thumb MCP joint.

Then the first web space is approached from both the ulnar thumb incision and the radial index finger incision. I place tissue into the proximal phalanx of the index finger across the first web space from the ulnar thumb incision. The first web space requires at least 1 cc of fat in most cases.

Next, the proximal phalanx of the index finger is approached with several passes made in a radiating pattern through each incision site. Only a minuscule amount of fat is placed with each pass in this area. By infiltrating fat from multiple directions, a “weaving” pattern of placement is created, thereby supporting the skin, in some cases all the way up to the proximal interphalangeal (PIP) joints.

Once fat has been grafted into the thumb and index finger, placement continues in minuscule increments over the index, middle, and ring fingers from an incision around the middle MCP joint. Care is taken to avoid placing fat over the joints, because the desired appearance is a reduction in the size of the joints. To cover the superficial digital veins and place fullness evenly around the MCP joint, fat should usually be feathered so it extends slightly past the proximal half of the proximal phalanx.

The little finger and ring finger are then infiltrated from the ulnar incision at the level of the MCP joint.

From the same ulnar incision, further placement can be made across the MCP joints all the way to the index finger. This allows more perpendicular placement, extending down along the distal web spaces, which frequently have thin skin and are wrinkled. Sometimes the unsupported skin may even fold over.

After fat is placed over the phalanges and into the distal web spaces, the spaces between the MCP joints are treated. Only a thin layer of tissue is placed over the MCP or PIP joints to avoid the appearance of enlarged joints.

Even after the insertion of as much as 7 cc of fat into the phalanges and web spaces of the fingers and thumb, the hand does not look overfilled, because the fat has been evenly distributed in a relatively thin layer.

Once placement of fat into the phalanges is completed, I return to the radial hand for more proximal placement. Using the radial thumb incision through which placement into the phalanges was begun, I radiate a pattern through the first web space over the thumb metacarpal almost to the palmar aspect of the radial hand. A number of passes made in a radiating fashion will be needed to place 3 to 4 cc of fat through any one incision.

The radiating pattern of placement can be clearly seen in this series of photographs depicting placement from the radial wrist incision. The placement begins at the radial hand at the juncture of the volar surface with the dorsal surface and progresses through the web space, over the dorsum of the hand and wrist, to the volar surface of the forearm. Four or more cubic centimeters of tissue may need to be placed over this area, with each aliquot of placement less than $\frac{1}{30}$ cc.

Next, the surgeon again approaches the more proximal placement into the first web space, radiating a pattern down across the dorsum of the hand.

A cannula is then inserted through the incision in the radial index finger at the level of the MCP joint. From here fat is placed through the first web space into the subcutaneous plane of the proximal phalanx of the thumb, radiating over the metacarpals of the thumb, index finger, and middle finger; fat is eventually placed proximal to the MCP joints of the fingers. The incision between the middle and the ring MCP joints is used to radiate a pattern of placement from the proximal index and middle fingers over the back of the hand to the proximal ring and little fingers.

Through the incision into the skin of the ulnar hand at the level of the MCP joint of the little finger, a pattern is radiated gradually almost to the ulnar aspect of the palm.

Then, from the ulnar wrist incision, a pattern of placement is radiated out from the ulnar wrist across the dorsum of the hand and wrist to the distal forearm. Usually fat is placed to cover the wrist and may even extend onto the distal forearm if the veins are bothersome in that area.

A curved Coleman style I or II cannula helps to navigate the contours of the hand and allows more controlled placement into the slightly deeper planes, such as when more tissue is needed in intermetacarpal depressions.

Every incision is sutured with 6-0 interrupted simple nylon. In this patient, a total of 28 cc of fat was placed into the right dorsal hand from the PIP joints to the proximal forearm. At the end of the procedure the hand is a little puffy, but not remarkably overcorrected. The extent of the area of grafting is adjusted until the physical appearance is pleasing, keeping in mind the patient's expectations.

Postoperative Care

Microfoam tape is placed on the skin of the infiltrated areas immediately after the procedure and left in place for 3 or 4 days as a protective barrier. A tight layer of Microfoam tape on the skin of the infiltrated areas will create a slight compression over the grafted areas, which may reduce edema. This tape also makes it difficult for the patient to touch the dorsal hand and inadvertently displace the newly placed fatty tissue through the loose areolar planes of the dorsal hand. Patients are instructed to avoid touching the backs of their hands for at least 1 week, particularly during sleep, and also to avoid sleeping with their heads against their hands. They are also told to keep their hands elevated above the level of the heart as much as possible and to use cold compresses as tolerated.

Problems and Complications

Edema is the most common postoperative sequela. Numerous passes with a cannula create substantial swelling in the dorsum of the hand, but bruising is surprisingly minimal after infiltration of fat with a style I blunt Coleman cannula. Within 2 to 3 weeks after the procedure, much of the swelling will have subsided, and although the hands may be a little puffy, they usually look natural and presentable.

Before 1992, I used sharp 16-gauge needles to inject lumps of fat into the dorsum of the hand and then massaged the fat into a smooth layer. Those patients experienced unpredictable results and noticeable lumps. Irregularities and migration have not been a problem since 1992, when I changed the placement technique.

The only other complication in the hand that I have experienced is unilateral scarring of the dorsal hand during a simultaneous chemical peel. I have not seen any bacterial or viral infections in patients with fat grafts to the upper extremities. I have also not seen a significant hematoma or even significant bruising in the dorsum of the hand when blunt cannulas are used, and patients have not complained of sensation changes. However, I have seen several patients in consultation after placement of fat into the dorsum of the hand by other physicians. Some of these patients had grafted fat located deep to the tendons, and fat even appeared to be present in the intrinsic muscles of the hand.

Results

Preoperative

2 years postoperatively

This 55-year-old woman presented with translucent skin through which one could clearly see the blue dorsal hand veins and glistening tendons. Fat removed from her love handles was processed down into usable tissue. At the same setting as a facial and neck procedure, 21 cc of fat was placed into the left hand and 25 cc was placed into the right hand. She returned 2 years later, extremely pleased with the way her hands looked.

Preoperative

39 months postoperatively

This 62-year-old woman presented with crêpinous of the skin of her hands and increasingly noticeable veins and tendons. She specifically wanted to place a small amount of fat onto the middle phalanx to decrease the boniness of her PIP and MCP joints. Twenty-nine cubic centimeters of refined fat was placed into her left hand and 28 cc into her right hand, from the distal forearm over the proximal phalanges and onto the middle phalanges, almost to the distal interphalangeal joint. The patient returned at 39 months, enthusiastic about her results.

Preoperative

1 year postoperatively

This 44-year-old man presented with the perception of thin forearms, which he thought made him look older and unhealthy. Eighteen months earlier, another plastic surgeon had placed AlloDerm into both forearms. The patient believed that the AlloDerm was completely resorbed within 6 months, although he had a hint of scarring in the midforearm. I layered 47.5 cc of refined fat into his right forearm and 50 cc in the left forearm proximal to the wrist over slightly more than half of his volar forearm. He returned at 1 year, delighted at the thickening of the circumference of his distal forearm and the smoothing of his volar forearm skin.

Nose

Fat grafting to the nose is an effective method for complementing rhinoplasty procedures. Fat grafted to the nose is surprisingly well integrated; the grafted fat assumes the structural qualities of the part of the nose into which it is placed. By filling and adding structural support, grafted fat can fill holes, alter the nose's contour, or add support to address a number of problems.

Aesthetic and Topographic Considerations

The aging nose loses fullness in the glabella and nasion more than in any other location. As this area atrophies, the remaining parts of the nose become relatively larger. Therefore the tip appears larger, and it may also seem to droop.

A frequent sequela of rhinoplasty surgery is an open roof in which the cartilaginous and bony parts of the nose have been repositioned so that they are no longer continuous. This leaves an open roof that is palpable and often even visible through the thin skin of the nasal dorsum. Deformation of the cartilage or bone occurs in other situations after rhinoplasties. The skin of the nose in some patients is so thin that irregularities can be amazingly visible, so that many malpositioned subcutaneous structures are painfully evident after nasal surgery.

Indications

The most obvious and simplest use of fat grafting to the nose is to fill in irregularities and divots. Placing a thin layer subcutaneously provides support for the skin and can disguise visible irregularities of the cartilage and bone. Concentrating the fat grafts into defined areas can improve the line of light reflection on the dorsum or subtly change the proportion of one part of the nose in relation to another part. The structural application of fat grafts can improve alar notching or close an open roof. Finally, structural fat placed in the nasal valve may act like a spreader graft to relieve nasal airway obstruction. But fat grafting to the nose does much more than fill defects: it provides soft tissue coverage of the bony and cartilaginous framework under the skin.

Anesthesia

Anesthesia is obtained in most cases with local infiltration of 0.5% lidocaine with 1:100,000 epinephrine and sedation. Epinephrine is useful for causing vasoconstriction, thereby decreasing the possibility of intravascular emboli.

Incisions

Incisions are usually made in the central forehead, medial eyebrows, cheek, or alar base and through the central lip.

Infiltration Cannulas

Infiltration into the nose is performed mainly with Coleman style III cannulas. The tip of the style III cannula helps push through the frequently encountered fibrous tissues of the nose, especially a nose that has scarring from a previous operation. Although I use straight cannulas most often, curved cannulas help navigate the curvature of the nasion and glabella as well as facilitating different approaches to the alae.

Mini Cannulas

Recently I have started using mini-cannulas. Although I still prefer the larger bore cannulas for many areas, I have changed to 19-gauge (external measurement) cannulas with a style III tip for most applications in the periorbital and nasal regions. These instruments are named *mini Coleman cannulas*.

Intradermal Infiltration

Deep dermal injection

Finally, I sometimes find intradermal infiltration of fat with a sharp needle helpful. This needs to be approached with great caution to avoid intravascular emboli.

Level of Infiltration

Fat is layered from the periosteum/perichondrium to the intradermal level.

In particular, a significant layer can be placed into the muscles of the upper nose, nasion, and glabella. Occasionally, fat can even be placed posterior to the cartilage to help expand the nasal valve, as a “spreader graft.”

Volume Ranges

The volume placed varies widely, depending on the defect being treated, but can be as little as 0.4 cc in the alar rim to as much as 9 cc in a saddle nose deformity.

Markings

These drawings are for a patient whose primary goal was to increase the projection of her nasal tip, but she understood that this was difficult to accomplish with fat grafting. She also wanted the nasal dorsum straightened more, with placement of more tissue down the center of the dorsum to obtain a more central light reflection. She also specifically wanted to have still less alar notching and more columellar show.

On the day of the procedure, the goals reflected in the blueprints are transferred to her nose using colored markers. Green marks indicate a planned structural change in the area. Blue marks indicate planned intra-dermal placement of fat as well as subcutaneous placement; orange marks are used to delineate the limits of placement (usually no fat is placed in the areas marked with orange).

Technique

The key to placement of fat into the nose is meticulous placement in every layer available: intradermal, subcutaneous, and intramuscular; into fibrous tissues; and above and even below the perichondrium and periosteum.

The dorsum is approached first with a curved Coleman cannula through the forehead incision. The fat in this case was layered beginning against the periosteum/perichondrium and gradually brought through the layers to the immediate subdermal layer.

Fatty tissue is then layered in a similar fashion into the right lateral nose deficiency through the same forehead incision.

The tip is approached through the same incision to provide the first direction for layering into the tip to try to increase tip projection.

From the alar base, tissue is layered for structural support into the area of alar notching. This structural approach should start at the alar rim through the middle alae. From this approach, further augmentation of the nasal tip can be attained to increase tip projection.

The right lateral nasal deficiency that was approached from the forehead now can be approached from the alar base. Adding a second direction of placement is always advised if possible.

Before proceeding with another direction of placement into the nose, the incisions already made should be closed to prevent leakage of the fat out the incision sites.

An incision is made in the vermilion of the lip to access the tip from another direction as well as placement into the columella to increase columellar show.

Intradermal injections into the central dorsum can sharpen the straight line of reflected light and add extra dorsal and maybe even tip projection.

Further support in the alar rim can be created by supplementing the subcutaneous placement with intradermal injection from a different direction. The surgeon should avoid injection into the deeper structures with a sharp needle to avoid intravascular cannulation of arteries.

Dressings

The appearance of the patient immediately after the procedure is shown. Reston foam is applied to the glabella and base of the columella and secured with Tegaderm to prevent migration of fat out of the directions of entry.

Postoperative Care

Dressings vary, depending on the specific procedure performed. The dressings are used to reduce migration of the fat out of the areas of placement through the placement tunnels. This can involve placing pressure between the incision sites and the area of infiltration, or providing protection to the nose (with a splint) to prevent manipulation of the newly transplanted fat. The patient should be told to avoid aggressively touching the nose to prevent fat migration.

Problems and Complications

Probably the most common problem after placement of fat is inadequate correction. Even if there is a significant improvement, patients usually want to have more. Patients must be prepared for the potential need for a second or even third treatment.

Intravascular injection is the most feared potential complication from injecting anything into the nose with a sharp needle. Care should be taken to inject epinephrine, remain at a superficial level, and place the fat in tiny aliquots when using sharp needles in the nose. Blistering that occurs 3 or 4 days after injection of any particulate substance into the nose is most likely an intravascular event, not an infection.

Results

This 56-year-old woman had had four rhinoplasties by plastic surgeons on both coasts of the United States, and silicone injections to her nose. She also had undergone two face lifts, a coronal brow lift, and, at least four times, fat grafting by another surgeon to her lower eyelids and cheeks. Surprisingly, she had undergone no blepharoplasties or any procedures to her upper eyelids, except for the brow lift.

A photograph of the patient when she was younger reveals a much softer nose and fuller periorbital region. Closing the open roof was a priority to visually connect the bony and cartilaginous portions of the nose. I planned reconstruction of the alar rim with an attempt at medialization of the nasal tip, as well as filling of the lateral osteotomy sites.

Markings delineate the planned procedure: 3.5 cc was placed into the dorsum first using a Coleman style III cannula, followed by 1 cc with a 22-gauge needle to increase the light reflection; 3.3 cc was placed into the right alar region and 2 cc into the left; 1 cc was placed into the lateral nose on each side, feathering into the lower eyelids. The adhesions were so strong that a V-dissection was necessary to release them.

Preoperative

6 days postoperatively

5 weeks postoperatively

1 year postoperatively

Comparison of these photographs reveals that the remarkable swelling and bruising present at 6 days postoperatively had resolved completely by the fifth week. The difference between the 5-week and 1-year follow-up is minimal; primarily there has been further softening of the osteotomy site corrections. The improvement of the peri-orbital region in general is evident, with remarkable improvement in the quality of the skin and lightening of the skin color.

Follow-up at 1 year after the fat grafting procedure demonstrates a remarkably normal-appearing nose. The bony portion of the nose flows more naturally into the cartilaginous area, with a more distinct central light reflection and far fewer irregularities.

The augmentation of the central dorsum connects the cartilaginous nose with the bony nose along the dorsum to allow a line of light to flow continuously from the nose to the nasion. In addition, structural augmentation of the alar rim pushes the nasal tip back to a more central, normal-appearing location. Curiously, the increase in the size of the rest of the nose makes the nasal tip appear much smaller, even though no tissue was removed.

This patient had undergone at least 12 previous nasal procedures, including placement and removal of Gore-Tex, numerous ear cartilage grafts, and not only autologous but also homologous rib cartilage grafts. With all of her procedures, she had sustained a large septal perforation.

The plan developed during earlier consultations was marked on her immediately preoperatively. The plan was primarily to create soft tissue coverage to disguise the many irregularities left from her previous procedures, especially the cartilage grafts.

The green markings indicate changes in shape, and the orange markings show the limits of placement. In the glabella the focus was on rejuvenation, calling for placement of subtle amounts over the entire area, from orange markings to orange markings, plus some placement directly into the skin of the frown lines (blue). Incision sites are marked in red in the forehead, medial eyebrow, anterior malar cheeks, and vermillion in the middle of the upper lip.

During the procedure, 0.5 cc was placed in each alar region with a Coleman style III cannula, and 0.5 cc was placed into the dermis of the columella with a 22-gauge needle. Into the dorsum 3.5 cc was placed with a Coleman style III cannula and 1 cc into the midline with a 22-gauge needle to increase the light reflection; 0.5 cc was placed diffusely with a Coleman style III cannula and 1.0 cc placed into the glabellar frown lines and the central vertical wrinkle into the skin with a 22-gauge needle. At the end of the procedure, a V-dissector was used to free up some of the scarring present between the skin and the underlying bone or cartilage.

One year after this procedure, softening of the angular edges from the nasal cartilage and bone can be seen, along with an apparent thickening of the skin, especially over the dorsum. The glabella is slightly fuller, with a diminution of the frown wrinkles. However, the wrinkles lateral to the areas of placement are more obvious. The lateral view shows that the amount of placement was minimal.

Lips

Structural fat grafting to the lips can produce long-lasting enhancement of the upper and lower lip with purely autologous material. Structural form is one of the primary considerations with lip augmentation. Consistently good results are obtained by placing tissue with careful attention to the effect that injected volume will have on ultimate lip shape.

Aesthetic and Anatomic Considerations

An attractive upper lip has a distinctly protuberant and continuous turgid white roll, which is separate from the skin of the lip. The white roll usually tapers off from peaks on either side of the Cupid's bow and becomes less obvious laterally. Cephalad to the white roll, the skin drops back from the protuberance of the white roll to begin the slight concave curve of the upper lip. The upper lip has two distinct philtral columns curving in a similar concave fashion from their origin where the white roll hits the peaks of the Cupid's bow to the columella. That curve is dramatically more concave inferiorly than superiorly. Under the Cupid's bow, the vermilion of the lip has a well-centered, distinct tubercle. That tubercle is the most caudal element of an attractive upper lip. Medial to each commissure is a fullness of the upper lip that is significantly less protuberant than the central tubercle in the vermilion. Between the central tubercle and the lateral fullness is a concavity or slight depression.

The lower lip has a slightly protuberant rim like the white roll of the upper lip, but less distinctive in color and turgidity. An attractive lower lip has elements that complement the upper lip, following the shape, but with the opposite components from the upper lip. A distinct central depression, essentially a cleft, is bordered on either side by tubercles significantly larger than the central protuberance of the upper lip. The alignment of the lower lip tubercles is oblique so that they push the central lip out into a distinct pout. The most important difference between the upper and lower lip in a normal, young mouth is that the amount of vermilion visible in the lower lip is much greater.

Placement of fat into different parts of the lip leads to different results. Particular attention should be paid to the level and anatomic areas into which the fat is placed. The goal of lip augmentation is to flip out the vermilion of the lips enough to create attractive, pouty lips with the least volume possible. This is accomplished by superficial layering of structural fat, primarily immediately under the mucosa and vermilion to increase the exposed surface area of the lip.

Because the goal is eversion of the vermilion of the lip, care should be taken not to place any support into an area that might oppose eversion. For instance, placement of fatty tissue deep to the cutaneous element of the lips will increase the structural support of the skin. This may soften some of the vertical wrinkles cephalic to the white roll or caudal to the rim of the lower lip. However, increasing the structural support of the skin will invert the vermilion of the lips, making them appear smaller.

Indications and Patient Selection

The primary indications for lip augmentation are aging and the patient's desire for adjustment of facial proportion. Often these two indications are present in the same patient. As a person ages, the lips lose subvermilion and subcutaneous fullness. This results in an inversion of the lower lip and deflation of the upper lip. As a person ages, the upper and lower lips usually become more similar in size on frontal view. The best candidates for lip augmentation are persons who had full lips when they were young. Restoring fullness to their lips will return them to their youthful state.

The most challenging patient is the one who never had full, attractive lips. In these patients, to create a full, attractive lip, the fatty tissue must be placed so that the vectors of placement overwhelm the patient's natural anatomic tendencies.

One of the most difficult patients is the one who has had placement of a nonintegrated, permanent soft tissue filler such as Gore-Tex, solid silicone, dermal fat grafts, fascia grafts, or other similar fillers. If these nonintegrated substances can be removed from the lip, I usually recommend doing so. In patients in whom I have left the substances in place, there remains an unnatural feel to the lip. Patients who have had injections into their lips of permanent fillers such as silicone, Artecoll, DermAlive, and polyacrylamide gel represent a different challenge. Because it is impossible to remove these substances, the surgeon who chooses to operate on these patients must devise a careful plan that will avoid making the lips look worse.

Anesthesia

Sedation is usually used in combination with local infiltration. In addition, 1% lidocaine with 1:100,000 epinephrine can be used for infraorbital and mental nerve blocks to further facilitate anesthesia; 0.5% lidocaine with 1:200,000 epinephrine

is infiltrated into the dermis at the incision sites before the incisions are made. Next, 0.5% lidocaine with 1:200,000 epinephrine is infiltrated into the superficial muscle and submucosal planes using a style III cannula, with placement of approximately 3 or 4 ml into each lip.

Incisions

The incisions for placement into both the upper and lower lip are most commonly made near the commissures of the lip entirely on the cutaneous lip. I will place the incision in a wrinkle line radiating from the lip. Occasionally I use the midmalar incision or mandibular incisions for placement of some of the tissue, especially to approach the cutaneous lips.

Infiltration Cannulas

The sharpest of the blunt cannulas, a style III infiltration cannula, is used almost exclusively for placement into the entire lip. This cannula allows me to place the refined fat with the greatest accuracy into the plane immediately deep to the mucosa or vermilion.

For an aging lip with wrinkling, I will often place 0.5 to 1 cc of fat using a 22-gauge needle injecting into the deep dermis and immediate subdermal space.

Level of Infiltration

Successful enhancement of the lip is not just a matter of placing a specific volume of fat into the lip. The level of fat placement is of paramount importance to consistently realize any planned changes.

Correct superficial fat placement

Almost all of the grafted fat should be infiltrated into the most superficial level, immediately deep to the vermilion and mucosa.

Volume Ranges

The suggested volumes of placement are as follows:

More than 0.75 cc but rarely more than 1.25 cc for restructuring the white roll

More than 0.75 cc and less than 1.25 cc in the lower lip rim

A minimum of 1.5 cc but rarely more than 4 cc into the body of the upper lip

Slightly more than twice the amount placed in the upper lip is placed in the lower lip body for the average patient

Technique

This 38-year-old woman presented for treatment of acne scarring. During her initial consultation, she noted that an attempt to augment her lips had been made in the distant past with intradermal collagen injections and requested a modest lip aug-

mentation to soften her lips and make them look less severe. She desired more vermilion show to her upper lip but wanted to avoid having too much of a flip in the upper lip because she did not want her lips to have an overly augmented, puffy look.

Markings

The green pen markings outline the plan for lip augmentation. The green line below the white roll shows the plan for placement into the vermilion below the white roll, not into the white roll. The placement caudal to the white roll will extend out almost to the commissure but will end approximately 4 mm before the oral commissures. The markings show that placement into the body of the lip will be emphasized centrally and laterally to create a distinct concavity of the area not marked in green.

The beginnings of the philtral columns are marked as a reminder that placement of the fat should be extended slightly into the base of the philtral columns to slightly increase their turgor. The lateral oblique “balls” of the lower lip are also marked. The lower lip placement is in the vermilion next to the cutaneous lip, with no placement at all deep to the cutaneous element of the lower lip. Slight depressions in the lateral cutaneous lip were identified in this patient and marked on the skin. This is the only place that structure will be placed under the lower lip cutaneous portion.

White Roll

I usually begin simple aesthetic augmentation of the lip by placing tissue into the area of the white roll. This area is the most difficult and requires the most precise placement. Although I commonly use the style III cannula for placement into the white roll, I occasionally will use a sharp needle to place a small amount into the deep dermis.

Access for the white roll placement is from the incisions near the lip commissures on either side.

After advancing the tip almost to the opposite commissure through the upper lip, the cannula is withdrawn slowly across the cephaladmost vermilion as gradual pressure is placed onto the plunger of the 1 cc syringe. The objective is to lay down a small (but sometimes as much as $\frac{1}{5}$ cc) increment of refined fat. In many lips, such as those shown above, the metallic tip can be seen shining through the vermilion caudal to the white roll as the cannula is withdrawn across the lip.

I usually approach the placement into the white roll from both lateral incisions. To add structure to the philtral columns, I divert the cannula up from the vermilion into the columns. This placement is also extremely superficial, and the tissue is placed immediately under the skin, avoiding insertion of fat directly into the orbicularis oris muscle when possible. I placed 0.8 cc of tissue into this patient's upper lip white roll.

Lower Lip

Although the lower lip does not have an actual white roll, the placement in the lower lip begins with an approach almost identical to that of the upper lip white roll. The graft is placed in the vermilion just cephalic to the cutaneous border using a style III cannula. Again the fat in the lip should be placed in the immediate subdermal layer. Although I advance the tip of the cannula all the way to the opposite commissure, I place most of the tissue along the lower lip rim into the central two thirds of the lip. An attractive lip is not excessively full all the way to the commissure. Care is taken to place this tissue extremely superficially and in the vermilion only.

The next consideration in infiltrating the lower lip is maintenance of a youthful shape. My first approach to the lower lip after establishing a turgid rim is to create oblong “balls” or protuberances on each side, just lateral to the center of the lip. In this patient an ipsilateral incision is used to place the left ball into the lower lip. As in most areas of the lip, the depth of placement is immediately under the mucosa and vermillion with a style III cannula. The key to this placement is central eversion of the lower lip while leaving a distinct deficiency, almost a cleft centrally. As always, the fat must be placed in miniscule amounts.

After an initial volume from one side is placed, a similar amount is placed into the opposite side through its ipsilateral incision.

At this point, 1 cc has been placed into each ball and another 1 cc into the lower lip rim.

As I continue to place tissue into the balls of the lower lip, I switch to the contralateral incision for placement of another volume on either side. This approach allows me to feather back into the mucosal lip with a structural layer.

The focus of vermilion augmentation of the lower lip is the formation of lateral oblong balls with a central deficiency or cleft. The focus of placement into the mucosa is to encourage a central pout or eversion of the lower lip. After establishing the shape of the lateral oblong balls in the vermilion, some central lip placement is feathered between the lateral balls. The objective of this maneuver is to force out a central prominent pout from the lower lip while creating the lateral oblong balls. A thin layer of tissue is placed all the way to the frenulum of the lower lip to encourage eversion of the lower lip.

After placement of 2 cc into each lower lip ball and 1 cc into the lower lip rim, the lower lip has a distinct central pout with lateral protuberances and a central deficiency.

Upper Lip

In the upper lip, placement starts in the central fourth of the lip with a style III cannula. The level is against the vermilion and mucosa centrally. The placement in the upper lip is in the same depth as the lower lip, but the areas into which the fat is placed are opposite of those used in the lower lip. The placement here continues where I left off with the white roll. In the central fourth of the upper lip, I infiltrate under the vermilion by repeated linear injections into a level immediately under the vermilion to create a layer of tissue extending from the white roll back into the mucosal lip almost to the frenulum. Everting the lip with the opposite hand allows more predictable immediate subcutaneous placement. Note the blanching of the mucosa of the right upper lip. Finally, the contralateral tubercle is approached in a similar fashion.

Preoperative

4 days postoperatively

7 days postoperatively

44 days postoperatively

The following volumes were used in the lips of this patient. Into the cutaneous portion of the upper lateral lip, 0.3 cc was placed on each side. Into the white roll of the upper lip, 0.8 cc was placed with a 22-gauge needle, and 2 cc was placed into the lip itself. Into the lower lip, 0.75 cc was placed with a 22-gauge needle, and 6.5 cc more was placed using a style III cannula. The patient is shown at 4 days, 7 days, and 44 days after treatment.

The patient returned at 4 months, extremely pleased with her result and appreciating that she had a better pout and fuller upper lips. To evaluate the lips on any patient, the mouth must be relaxed and the lips not touching each other. I find that having the patient purse the lips allows a different evaluation of the volume of the lips.

Posttreatment Care

No dressings are used on the lips. Patients are told that the wet mucosa will undergo keratinization and become dry mucosa or vermillion. During this process, the lips may peel like a snake shedding its skin. Moisturizers or ointments are helpful during this process. The patient is asked not to massage the lips in the first weeks; however, the patient is encouraged to move the orbicularis oris in an attempt to promote lymphatic drainage. There are no further restrictions on lip motion after the procedure.

Recovery from fat grafting in the lips is usually the most difficult, in terms of the degree and duration of swelling, until it resolves sufficiently for the patient to return to daily activities. Cold or iced dressings (frozen peas or crushed ice in Baggies) are therefore of the utmost importance on the lips and should be actively encouraged.

Problems and Complications

In my experience rupture of the skin of the lower lip has occurred several times. This is a situation in which tension placed on the lower lip creates enough internal pressure to cause spontaneous lacerations that split open the lip in several locations. Such lacerations are closed with simple interrupted sutures. Because this lip splitting has occurred only in the lower lip, when it does occur it has become the volume-limiting factor in that case. For that reason, I usually start placement into the body of the lower lip before the body of the upper lip. Other possible but unusual complications include scarring, pyogenic granulomas, infection, and lip necrosis.

The mouth is one of the most likely sources of contamination. Therefore I am especially concerned about transporting bacteria, fungus, virus, or mycobacteria from the mouth to other sites and delay placement of tissue into the lip until the last step of any facial procedure. Any time I make an incision near the lip, I give prophylactic antibiotics (usually intraoperative cephalosporin). Eight years ago I started having patients gargle with Peridex preoperatively. Since that time, I have seen only one minor perioral infection.

Results

This 50-year-old patient presented with lips that were already aesthetically appealing but no longer as everted as when she was young. The lower lip was no longer the dominant larger lip, and the upper lip was not as full as when she was young.

As always, more attention was directed to planning the shape than in considering the volume. The markings made on the patient's lip reflect the plan. The approach to the lower lip emphasizes the dramatic eversion of the central lip while minimizing placement into the central lip. This is accomplished by primary placement into the previously described oblong balls of the lower lip. The alignment of these oblong structures is such that their axes converge above the most protuberant point of the pouty lower lip. On this patient, the upper lip markings were drawn to emphasize eversion of the central tubercle of the upper lip. However, some eversion of the lateral upper lip is desirable. It is this eversion of the lateral upper lip vermilion show that establishes the apparent width of a lip.

A total of 6 cc was placed into the lower lip. Into the upper lip, first 1.1 cc was placed caudal to the white roll, then 2.5 cc was placed into the upper lip, emphasizing the central and lateral tubercles, but with some fat placed in the concavity between them. Finally, 1.4 cc was placed to emphasize the philtral columns.

4 days postoperatively

17 days postoperatively

1 year postoperatively

Swelling at 4 days and 17 days after surgery is alarming to the patient. I always warn them that they will not look recognizably human but more like a monster for at least a week. Recovery from fat grafting in the lips is the most difficult, because it can be up to 4 weeks before the patient feels somewhat comfortable. Although visible swelling in this patient had completely resolved by 3 months, she claimed to feel changes in the texture as well as the size of her lips for up to 8 months.

Preoperative

1 year postoperatively

8 years postoperatively

The patient returned after 8 years with little if any change from her first year follow-up. She had had no procedures performed on her lips and had no fillers placed. She maintained obvious eversion of the lips in good form. If anything, her lips are slightly more everted than I would want. In the last few years I have tended to place less fatty tissue, trying to emphasize eversion over volume. If I were to augment the lips on this patient now, I would place less than half of the 1.4 cc placed into the philtral column and I would place less than 1 cc into the area of the white roll.

The ring flash oblique views allow a different analysis of the augmentation. One can see that despite the sizable volume added to the upper lip, there appears to be more incisor show as the lip is everted. In addition, the length of the upper lip is shortened both by the eversion and by the relative increase in the vermillion of the upper lip, which makes the cutaneous portion less of the overall lip.

Nasolabial Folds and Marionette Grooves

Fat grafting is also an effective method for treating nasolabial folds and marionette grooves. The key to fatty placement in these folds is infiltration of areas rather than individual lines. The focus is on placement over a general area to add support to the facial structures and improve the quality of skin.

Indications and Patient Selection

The primary indication for correction of the nasolabial folds and marionette grooves is aging. Older patients object to the expressions that age seems to have painted in the folds and lines on their faces; these appear more prominent and objectionable with each passing year. Younger patients who have deep nasolabial folds have a similar reaction when they perceive that their deeper-than-usual folds make them ap-

pear older than they are. The most important consideration with nasolabial folds is to be certain that the patient understands that the folds in the marionette area will not disappear. Improvement in the texture of the marionette grooves is frequently the best improvement possible with subcutaneous placement of fatty tissue. Collagen or hyaluronic acid may be indicated for additional blunting of the fold.

Anesthesia

One percent lidocaine with 1:100,000 epinephrine can be used for infraorbital and mental nerve blocks to facilitate anesthesia; 0.5% lidocaine with 1:200,000 epinephrine is infiltrated into the dermis at the incision sites before the incisions are made. Next, 0.5% lidocaine with 1:200,000 epinephrine is infiltrated into the nasolabial and marionette regions using a style II cannula.

Incisions

Lower midmalar incisions provide access for the perpendicular placement of tissue, and an incision in the lateral chin or mandibular border provides access for the longitudinal placement of tissue. Frequently an incision near the commissure is used for a different angle of placement.

Infiltration Cannulas

In the nasolabial fold there is little possibility of damage to any underlying structures, so Coleman style II is the most common cannula used in this area; a Coleman style III cannula may be used in areas of very fibrous adhesions, especially against the skin.

Level of Infiltration

The primary level of placement is immediately subcutaneous to deliver structural integrity to the cutaneous element of the fold. However, for deeper folds and premaxillary deficiencies, placement in the deeper planes may be indicated, especially in the nasolabial folds.

Volume Ranges

Volume ranges vary:

For correcting a minimal line in the nasolabial fold, as little as 1 cc is sometimes needed.

For deep nasolabial folds that have a significant premaxillary deficiency, infiltration with as much as 10 or 11 cc is required.

Marionette grooves can be corrected with as little as 0.5 cc, and rarely more than 3 cc is needed.

Care should be taken to avoid overfilling of the nasolabial or marionette regions. In the quest to eliminate folds, unnatural fullness can be created.

Technique

The markings are made with arrows pointing to the depth of the nasolabial fold crease, indicating the need for filling either on both sides of the crease or in the premaxillary region. In the premaxilla and marionette region, I usually fill from the medial area to the crease.

The syringe plunger is pressed minimally with each retreat of the cannula to express a small line of fatty tissue into the area of the nasolabial fold. Approximately $\frac{1}{10}$ to $\frac{1}{30}$ cc is expressed with each retreat of the cannula in this area.

Cephalad, the fat is placed medial to the folds. Only minimal fat is placed lateral to the fold, because the area lateral to this part of the nasolabial fold is usually already fuller than the patient desires.

A good deal of attention is paid to treating creases medial and lateral to the existing nasolabial folds and crease. Correction of the fold without infiltration of surrounding tissues will serve to accentuate preexisting minor creases. Next, the nasolabial fold is infiltrated from below to complement the structural placement of the transverse elements of fatty tissue. Although the cheek approach is the most important direction for placement of fatty tissue, placement of fat in a longitudinal direction allows a more precise volume correction immediately against the crease of the fold itself and adds structural integrity.

From the same cheek incision site that was used to place the fat perpendicular to the nasolabial folds, I begin the approach to the marionette region. Again placement is guided with the opposite hand with attention to avoiding perforation of the oral mucosa. Often infiltration of the marionette groove is continuous with the lateral mental region.

The marionette area is approached from many directions: it can be infiltrated from the chin, oral commissure, or the lateral mental region as well as the cheek. The aim of this multidirectional approach is to improve the texture of the region and to provide structural integrity to slightly elevate the corners of the mouth. The surgeon must avoid overfilling the marionette region with subcutaneous placement. Often a small amount of intradermal injection of fillers or fat can improve the result from subcutaneous placement.

Posttreatment Care

One layer of 1-inch Microfoam tape is used as a dressing for the nasolabial and marionette grooves. Recovery from placement into the nasolabial fold and marionette grooves is usually better tolerated than placement into other areas such as the lips or periorbital region. Bruising is often minimal, and the swelling usually looks acceptable within a few days. I do not recommend massage of the nasolabial and marionette areas.

Complications

The most common complication after ablation of the nasolabial fold is the formation of folds medial or distal to the old folds. That is why surrounding structures should be feathered or infiltrated when indicated.

Results

This early patient is shown before and 9 years 3 months after injection of fat using a 16-gauge sharp needle. I injected only 4 cc into each nasolabial fold from one direction (inferiorly).

Changes in this patient are typical of those commonly seen after nasolabial fold correction. Although there is a significant improvement, it is not the stereotypical change often anticipated by most surgeons who perform intradermal injections. The most consistent change observed after placement of a volume of fat into the subcutaneous planes of the nasolabial folds is that the fold moves forward on the face to be further away from the underlying bone and dentition. The mass effect of the diffuse placement of fatty tissue blunts the crease of the fold, but a slight fold remains. This type of fold is usually present in youthful photographs of patients. There is also a texture change in the area of the fat infiltration with a decrease in fine wrinkles and pore size. Even with careful feathering, some increase in the wrinkling of the skin can be seen where the feathering ends, especially in the medial marionette region. If patients desire a greater change to specific folds or wrinkles, adding additional fullness can sometimes help.

Clinical Caveats

Fat is living tissue that must be in close proximity to a nutritional and respiratory source to survive.

Maximizing the surface area of contact of each parcel of fatty tissue with the surrounding host tissues is essential for successful integration and anchoring of the newly placed tissue and to structurally manipulate the host tissues.

Incisions are placed in wrinkle lines, in folds, or in hair-bearing areas such as the eyebrow, sideburns, or pubic hair when possible. This facilitates placement of the fatty tissue in at least two directions when indicated.

To strengthen bony or underlying support, the fat can be layered in the deeper levels against the bone or cartilage. To support the skin, improve texture and color, and achieve a more aesthetic external appearance, the fat is layered immediately under the skin. For filling, plumping, or restoring fullness, tissues are placed in the intermediate layers between skin and the appropriate underlying tissue.

Hands

Placement of lumps of fat that the surgeon then tries to smooth out is the most likely technical error encountered in treatment of the hands. With the normal edema that is present, the surface of the hand may appear smooth, but as the edema resolves over the next 12 weeks, the irregularities become visible through the thin skin of the dorsum of the hand.

On palpation, fat parcels placed next to skin will feel like thicker skin, not like fat under skin.

Placing fat in a structured fashion with many minuscule tunnels of parcels of fat over the dorsal hand creates underlying support as well as a radial expansion of the skin.

Nose

Hydrodissection of the alae is often helpful before placement in that region to prevent perforation of the mucosa. This is especially important in scarred noses.

Even in the nose, it is important to try to place tissue from two different directions.

Blistering in the nose after injection of any filler or fat using a sharp needle is likely to be caused by intravascular injection.

The corrections with structural fat grafting are so natural (and often subtle) that the patient has trouble seeing them. Therefore it is essential to document the patient's preoperative appearance and postoperative condition so he or she can appreciate the change.

Lips

When performing several procedures, the lips are saved for the very last step to avoid contaminating the other areas of the face or body.

To accomplish lip augmentation with increased vermilion show, fat should not be placed deep to the cutaneous portion of the lip, because it can expand it and actually decrease the amount of vermilion show.

Because the white roll of the upper lip does not extend all the way to the commissures, placement of fat to strengthen or recreate a white roll should not be extended all the way to either lateral commissure.

Small lumps are amazingly well tolerated in the lip. Large ones are not.

Nasolabial Folds and Marionette Grooves

Correction of a fold without infiltration of surrounding tissues will accentuate pre-existing minor creases.

The marionette region should not be overfilled, because the grooves can easily be enlarged in some individuals.

Annotated Bibliography

Aboudib JH Jr, de Castro CC, Gradel J. Hand rejuvenescence by fat filling. *Ann Plast Surg* 28:559-564, 1992.

The authors review the advantages of fat filling for hand rejuvenescence. A highly satisfactory rate was obtained (98.62%) with a low complication rate (4.15%).

Carpaneda CA, Ribeiro MT. Percentage of graft viability versus injected volume in adipose autotransplants. *Aesthetic Plast Surg* 18:17-19, 1994.

This article discusses the spherical and cylindroid models to correlate the volume and the percentage of graft viability to the initial injected volume in adipose autotransplants. The authors concluded that the percentage of graft viability depends on the thickness and the geometrical shape, and is inversely proportional to the graft diameter if grafts with a diameter greater than 3 mm are considered.

Chajchir A, Benzaquen I. Liposuction fat grafts in face wrinkles and hemifacial atrophy. *Aesthetic Plast Surg* 10:115-117, 1986.

The authors present the idea of correcting soft tissue defects with an injection of fat obtained by liposuction. The technique is described and the results are demonstrated in several patients treated over a period of one year.

Coleman SR. Hand rejuvenation with structural fat grafting. *Plast Reconstr Surg* 110:1731-1744; discussion 1745-1747, 2002.

A simple, reliable technique of autologous fat grafting for long-lasting rejuvenation of the dorsum of the hand is presented.

Coleman SR. Structural fat grafts: The ideal filler? *Clin Plast Surg* 28:111-119, 2001.

The author describes the characteristics of fat as an ideal filler and the keys to the technique behind successful fat grafting.

Guerrerosantos J. Autologous fat grafting for body contouring. *Clin Plast Surg* 24:619-631, 1996.

In trying to achieve symmetry and better contour of the back torso and middle third of the body, the combination of liposuction and lipoinjection is rapidly becoming the procedure of choice. The indications and operative and postoperative techniques are detailed in this article. Fat graft long-term survival is presented.

Niechajev I, Sevcuk O. Long-term results of fat transplantation: clinical and histologic studies. *Plast Reconstr Surg* 94:496-506, 1994.

This article discusses nine cases of idiopathic constitutional subcutaneous fat atrophy in the cheek area during 1988-1992 that were treated by the autologous transplantation of fat for purely aesthetic reasons. Results and long-term follow-up are presented. Contrary to the experience of others, only the partial resorption of the transplanted fat occurred. This result was verified by six biopsy specimens obtained 7 to 36 months after transplantation.

Roundtables in Plastic Surgery. Tissue Fillers in Plastic Surgery, vol 1, no 2. St Louis: Quality Medical Publishing, 2004.

A panel of experts discuss the current options in synthetic and biologic tissue fillers as well as autologous fat grafting, their efficacy, clinical applications, and pitfalls. Case examples and results are included.

CHAPTER 14

Dermabrasion

JAMES L. BAKER, JR.

Aging of the skin is affected by both intrinsic and extrinsic factors. Intrinsic aging consists of endogenous influences such as genetic sequence, chronologic aging, skin laxity, and fine wrinkles of the skin *not* exposed to the sun. Genetic factors in combination with ultraviolet (UV) radiation exposure can affect the degree of UV radiation damage. Race, ethnicity, eye and hair color, and freckles all contribute to early onset of skin aging. Extrinsic aging and photodamaged skin are the result of chronic exposure to UV radiation, one of the major reasons why skin ages. Other factors leading to extrinsic aging include the type of clothing a person wears, where a person lives, and his or her occupation, lifestyle, age, and geography.

Photodamage is cumulative, from the first day of exposure until death. Fifty percent of a person's exposure to UV radiation occurs before 18 years of age. From the first moment a baby is taken outdoors, all subsequent outdoor activities will increase his or her likely radiation exposure. The working environment also influences exposure potential. Exposure decreases for people who work in an indoor environment. Occupations that require outdoor exposure will increase the photoaging process, particularly in unprotected skin. The key to diminishing this damage is education and the use of sunblocks.

Environmental factors such as heat, wind, humidity, pollutants, cloud cover, season, time of day, and reflected sunlight from the sand or snow also play a major role in radiation exposure. UV radiation increases with decreasing latitude and is compounded 4% for every thousand feet above sea level. Therefore skiing on Vail Mountain at 10,000 feet would increase the UV radiation exposure 40% over a visit to Walt Disney World in Orlando, Florida, which is at sea level.

Evolution of Technique

Removal of the upper layer of the skin for improvement in surface texture probably began in Egypt in 1500 BC, when a type of sandpaper was used by Egyptian surgeons to smooth out scars. In 1905 Kromayer, a German dermatologist, used a motorized dermabrader. This instrument used rotating burrs, which could remove the skin at various depths. Kromayer noted that ablation of the reticular dermis would result in healing with no scar. In 1947 Iverson, an American plastic surgeon, applied sandpaper abrasion for acne scars and traumatic tattoos. This technique was similar to the one used by Egyptian surgeons. Kurtin in New York, in collaboration with Robbins, modified power dental equipment for use in dermabrasion. Robbins also developed the diamond fraise, which is widely used today for dermabrasion. In 1985 Silverman et al advocated the use of prophylactic oral acyclovir for patients at risk for developing *Herpes simplex labialis*. Oral antiherpetic prophylactic medication is now a standard in skin resurfacing. In 1995 Tsai et al proposed using aluminum oxide crystals in a microdermabrasion instrument for superficial rhytids.

The current dermabrasion technique, which has evolved from its inception 3500 years ago, employs a small, handheld electric-powered instrument that rotates a wire brush or diamond fraise at speeds of 15,000 to 30,000 rpm. Either sedation with local anesthetics, topical spray refrigerants, or general anesthesia is necessary; the procedure is commonly performed as an outpatient procedure. The abrasion can be precisely controlled and results in an open wound that heals with reepithelialization after a relatively short period. Preventing infection and achieving rapid healing requires attention to detail for basic wound care. A variety of “artificial skin” materials can be used to diminish the discomfort of the operative site after the procedure and to promote wound healing. Products such as N-Terface (Winfield Laboratories, Inc., Richardson, TX), a polyethylene mesh developed as a cover for burn wounds, have been very useful.

In the past decade, incorporating some of the concepts of traditional dermabrasion, the new technique of microdermabrasion has been advocated. Microdermabrasion can improve certain types of scars from aged and sun-damaged skin while avoiding many of the problems seen with traditional dermabrasion. The technique uses a fine beam of aluminum oxide microcrystals to precisely and superficially peel the skin surface. Its advantages are that it is gentle and requires no significant change in the patient’s normal routine or activities. However, multiple treatment sessions are needed for optimal improvement.

Despite the initial popularity of skin-resurfacing CO₂ lasers over the past decade, dermabrasion remains a safe, efficacious, and inexpensive method of skin resurfacing with very predictable outcomes. A complete dermabrasion setup will cost less than \$1000, whereas most resurfacing lasers cost in excess of \$50,000.

Pretreatment Assessment

When dermabrasion is used as an adjunct to facial rejuvenation, the patient’s motivation is well documented and justified. Perioral rhytids are effectively treated with dermabrasion, and the results are predictable and satisfactory. For deep rhytids, only phenol chemical peeling can produce a superior result. However, the hypopigmentation that usually follows phenol peels is undesirable, especially in patients with Fitzpatrick skin types III or IV.

Because of the surgeon’s ability to control the depth with dermabrasion, hypopigmentation is usually avoided. Deep rhytids respond better to dermabrasion than to CO₂ laser resurfacing, with less potential for prolonged recuperation and/or hyperpigmentation, hypopigmentation, or scarring.

When using dermabrasion for improvement of postacne scarring, the surgeon must evaluate the patient carefully from a psychological standpoint to avoid unrealistic expectations of what the procedure can accomplish. It is very difficult to make the patient understand that scarring is permanent, and dermabrasion can only improve the amount of light and shadow that falls on the craters of the skin. Dermabrasion will produce a more undulating surface as opposed to a rocky, craggy type of dermis. Scars, although they are improved, will not be removed, and the patient should never expect to have the skin restored to the soft smooth texture of infancy. It should be stressed that two or three procedures are necessary for maximal improvement, and it will be an improvement, but not a cure.

Patients to avoid are those who exaggerate a tiny or barely visible defect, such as a small scar, and those who are unable to describe what they expect from the procedure (that is, their desired change). If the surgeon has trouble establishing good rapport with the patient, it is best to decline to treat that person. Surgeons should also be wary of patients who have had two or three procedures performed by different plastic surgeons and criticize all of their results. These patients come to you because they have heard that you are “the best.” If you operate on this type of patient, his or her eventual disillusionment and dissatisfaction following your procedure are predictable.

The extent of the procedure and the areas to be treated should be marked on a face diagram to ensure that the patient understands exactly what areas will be addressed with the procedure and where improvement should be expected. Darker areas can easily be noted with the use of colored marking pens or highlighters. Photographic documentation is mandatory, despite the difficulty in demonstrating skin pits and scars with photography. If lines are extremely deep, it is likely that neither laser resurfacing nor dermabrasion will completely eradicate them, and the possibility of a later treatment with a tissue filler should be discussed. This type of advance preparation should help to adequately inform the patient about what to expect and help to prevent patient disappointment. For this reason and to facilitate compliance, it is extremely important for the patient to understand postoperative care. It normally takes a week before healing is completed, and the patient’s role in wound care is of the utmost importance. The treated area needs to be kept clean and moist with a recommended skin ointment. Sun exposure must be avoided, and the use of sunblocks is mandatory until normal color returns.

ANATOMIC FORM

Name _____ Date _____
LAST FIRST MIDDLE

Patients taking isotretinoin (Accutane) or those who have recently completed a course of Accutane therapy should not undergo any skin-resurfacing procedures for at least 6 months after completion of their therapy. Accutane will act as an inhibitor of pilosebaceous gland function, which is necessary for reepithelialization. I prefer to wait at least 1 year, and ideally, 2 years after Accutane therapy to ensure that pilosebaceous gland function has returned to normal. Because of the paucity of these glands below the mandibular rim, dermabrasion of neck rhytids should also be avoided.

This 52-year-old woman underwent a face lift and attempted removal of neck rhytids by dermabrasion. The result was hypertrophic scarring of all areas treated on both sides of the neck.

This example illustrates why dermabrasion on the neck should not be attempted because of the paucity of pilosebaceous glands, which are needed for reepithelialization.

A complete physical examination is essential, and any health problems should be carefully evaluated. The patient's history of cigarette smoking and alcohol intake should be weighed as to their possible deleterious effects on wound healing. Allergies and medications should also be carefully evaluated.

Fitzpatrick Skin Care Classification

The Fitzpatrick classification system of sun-reactive skin type is a good measure of ideal candidates for skin-resurfacing procedures. Although those with skin types I to III are considered the ideal patients for a predictable outcome for dermabrasion and other resurfacing procedures, those with type IV skin can anticipate a good result with the use of bleaching creams applied both preoperatively and postoperatively to diminish melanocytic activity. However, it should be discussed with these patients that they are more prone to hyperpigmentation problems postoperatively and, of course, all patients undergoing skin resurfacing should be advised to avoid sun exposure or tanning booths until normal color returns. Sunblocks with an SPF of 35 or higher are recommended, and patients should be advised not to sit near a swimming pool or go to the beach because of the reflected UV radiation coming off the water. The sun's rays can also attack the skin even when an individual is wearing a wide-brimmed hat. Boating is also contraindicated during this period for the same reason.

Fitzpatrick's Classification of Sun-Reactive Skin Types

Skin Type	Color	Reaction to First Summer Exposure
I	White	Always burns, never tans
II	White	Usually burns, tans with difficulty
III	White	Sometimes mild burn, tanning moderate
IV	Moderate brown	Rarely burns, tans with ease
V	Dark brown*	Very rarely burns, tans very easily
VI	Black	No burn, tans very easily

*For example, East Indian, Asian, Hispanic, or light African descent.

Skin care counseling with the continued use of alpha-hydroxy acid products and sun-blocks should be a part of the routine discussion and recommended regimen for the patient to ensure the longevity of the procedure. Perioperative use of systemic antibiotics as well as an antiviral medication (acyclovir) is strongly recommended, even without a direct history of a “cold sore” that the patient can recall. Many patients have had inoculation of the herpes simplex labialis virus in childhood and may not remember having had an attack. When it comes to prophylactic use of acyclovir drugs, the familiar expression, “An ounce of prevention is worth a pound of cure,” is sound advice.

This 42-year-old woman underwent perioral dermabrasion for rhytids before prophylactic acyclovir therapy. She gave no history of “cold sores” at any time during her life. A single lesion of herpes simplex occurred in the central portion of her upper lip 5 days after dermabrasion. Her outbreak was treated with acyclovir without sequelae. It is recommended that all patients, despite a negative history, be placed on prophylactic acyclovir therapy for any resurfacing procedure.

For patients with skin types V and VI who are contemplating dermabrasion, it is important to first perform a test spot at the hairline. Although this preliminary test can give an indication of the expected result, there is no 100% guarantee that the remainder of the facial skin will respond identically, and the patient should be forewarned of this.

Healing of the Dermabrasion Wound

Although dermabrasion can be performed to any dermal level by control of the surgeon's hand, most procedures are targeted to a specific level of the dermis. Deeper rhytids require a greater depth of wounding, and it is not the ablation of the abnormal epidermis that creates the result but rather the stimulation of dermal fibroblasts, which lay down collagen that creates the improvement. Healing is expected in 7 to 10 days.

Healing of dermabraded areas is similar to that of split-thickness skin graft donor sites. Initially there is an outpouring of serum, which forms a coagulum that covers the abraded surface, trapping necrotic and other cell debris. Immediate activity begins in the adnexal cells adjacent to those exposed by the dermabrasion. These exposed cells undergo necrosis, and those below take on several of the attributes of squamous epithelium. Marginal epithelial cells migrate from the edges of the abraded areas, and within 3 days new epidermal cells are seen growing across the surface and extending out from these adnexal components. By the fifth postoperative day, epidermal regeneration is usually complete. It is thin, lacks rete pegs, but exhibits developing hair follicles and sebaceous glands. These elements not only contribute to the epithelial resurfacing but are also evidence that functional activity is resuming.

The period required for complete epidermal regeneration is usually between 5 and 7 days. In the newly regenerated dermis, young fibroblasts are seen lying with their long axis in a horizontal plane and new capillary development is noted. Collagen is being laid down by the second week. This new collagen shows a horizontal striation that can last for 3 to 4 years following dermabrasion. It is this new collagen that fills out the skin, resulting in the youthful rounded appearance frequently witnessed after dermabrasion procedures. Moisturizers are recommended to keep the new skin hydrated, and sunblock is mandatory to diminish the possibility of hyperpigmentation.

In the first month there is little evidence of pigment formation in the basal layers of the epidermis. After 1 month, however, some return of fine pigment granules can be noted. With the newly healed postoperative skin, exposure to sunlight intensifies the potential for hyperpigmentation even in patients with Fitzpatrick skin types I to III. It can last from 3 months to several years and occasionally can be permanent.

Treatment for the prevention of hyperpigmentation consists of an SPF 30 or higher sun protection as well as vitamin C tablets (2 g ascorbic acid daily) to inhibit melanin formation, either topical steroids, or in developing cases of hyperpigmentation, 25 mg of cortisone daily to inhibit the pituitary melanocyte-stimulating hormone. Hydroquinone is also indicated to inhibit melanin production by the melanocyte.

Milia are small white-headed cysts arising from the epithelial cells of the hair follicles, sebaceous gland ducts, and sweat ducts that have been sealed over at the time of surgery and have become isolated under the newly epithelialized surface. They usually appear within the first month following the procedure. These can be treated with an exfoliating buffing pad or mild abrasive facial scrubs to unroof the blocked ducts.

This 20-year-old woman underwent full-face dermabrasion for acne scarring. Milia were noted 8 days after the procedure and were attributed to the epithelial regeneration covering the small oil gland ducts. This was successfully treated with gentle abrasion using a buff puff to unroof the small cysts. Prophylaxis is difficult, but treatment is simple.

Equipment

This is a typical small, self-contained dermabrader. There are several units to choose from commercially. They are ideal for office use, because they require limited space for storage or operation and can be easily cleaned with the handpiece being sterilized. Either wire brush or diamond fraise drums are used. I prefer the diamond fraise, be-

cause I am familiar with its operation; I have used it with satisfactory results over the past 35 years and find that it makes it easier to judge the depth of treatment. The diamond fraise is available in different surfaces, from fine to extra coarse. For aesthetic surgery most surgeons prefer medium to coarse, plus a touchup of the finer rhytids with a fine diamond fraise.

Although the small hand engine–type dermabraders have a knob to control the speed of the drum rotation and an on/off switch, this limits the surgeon's control during the procedure. I prefer a foot pedal rheostat, which allows me a wide range of speeds under my total control during surgery. For operating room use, an electric dental motor with a handpiece will provide an unlimited number of years of use with minimal cost or downtime for repair. These motors are extremely reliable and inexpensive.

For the past 20 years I have used a Foredom Electric Series S-Engine Motor Style CC with handpiece No. 7D (The Foredom Electric Co., Bethel, CT). The cost is several hundred dollars, and the dental handpiece is very easy to hold and control. A diamond fraise 17 by 10 mm or 17 by 14 mm is used with coarse, regular, or fine surfaces.

Technique

Preoperative treatment consists a broad-spectrum antibiotic administered intravenously just before the procedure, or given orally beginning the day before the procedure, and continuing for 1 week postoperatively. An acyclovir preparation such as Valtrex (500 mg twice a day) or Zovirax (400 mg three times a day) is administered the day before surgery, *as well as the morning of surgery*, and is continued for 7 to 10 days postoperatively. The skin is cleansed with an antibacterial soap in the operating room. Either general anesthesia or local anesthesia with nerve block and se-

dation is used. This is a matter of personal choice, and the decision is made by the surgeon and the patient. Anesthesia equipment should be covered to prevent blood spray from contaminating the equipment, and precautions should be taken by the anesthesiologist and the nursing personnel. Magnifying loupes are used not only to magnify the surface of the skin and the rhytids but also to help protect the surgeon from blood spray. The surgeon's eyes should be covered with some protective eye shields, in any event. If acne scars are being addressed, it is helpful to mark the pit of the scar with a surgical marker and outline the area of maximal scarring. This will be helpful in determining the depth to which dermabrasion will be done. It can also be performed with deep rhytids, placing a line at the base of the depth with a fine-point marker.

Because the drum is rotating in a clockwise direction, the drum should always be moved toward the leading edge of soft tissue. With the drum rotating counterclockwise, the hand moves the dermabrading instrument over the cutaneous junction edge to avoid avulsion of the lip. This is very important, especially when trying to treat crow's-feet.

The rotating motion of the drum is used to obtain a smooth surface. Great care must be taken in holding the sponge in the opposite hand a safe distance from the rotating drum. Once the gauze is impregnated with blood, it is very easy to have an edge of the gauze get caught in the fraise or wire brush and torque into the patient's face. This could cause severe eye or soft tissue damage from the whiplike effect of the end of the gauze. The abrader is moved slowly back and forth or in a circular motion across the surface, abrading through epidermis down to the desired level of the dermis.

The bleeding pattern is a good indicator of depth. The skin should be wiped frequently so this bleeding pattern can be observed. Care must be taken to not angulate the fraise or wire brush because the leading edge can cut into the skin surface and cause undesired pitting, grooving, and/or scarring. It is critical to maintain the drum parallel to the skin surface.

When working around the lips, the speed should be reduced and the drum pulled softly over the vermillion-cutaneous junction to avoid avulsion of the lip edge. When nasolabial folds are being dermabraded, the drum should rotate away from the edge of the nose and toward the soft tissue angle at the bottom of the rhytid. The same caution is necessary when dermabrading crow's-feet near the eyelids. *The rotation of the drum should always be toward the leading edge of any soft tissue.*

After the desired depth in the dermis has been achieved, the dermabraded areas should be thoroughly cleansed with saline solution using a soft bristle brush or rough gauze. This will remove the excess skin debris. To diminish bleeding, a sponge soaked in saline solution with epinephrine in a 1:1,000,000 dilution is helpful.

The operative site can then be treated open, with the application of antibacterial or Aquaphor ointment or with a layer of Adaptec or Telfa. For the past 15 years I have preferred to use N-Terface, which is a polyethylene mesh developed originally for the treatment of burn patients. Strips of this nylonlike material are cut to fit over the treated areas, and a layer of Aquaphor ointment is applied. This diminishes the postoperative discomfort considerably, and the material will separate on its own as reepithelialization occurs, which is usually 5 to 7 days. Patients may shower with the material in place and are encouraged to trim loose edges as healing progresses. It will eventually soak off with gentle soap and water application. For many years, thymol iodide powder was used to dry the operative site; however, as this dried to a stiff crust, it was not only uncomfortable but looked unsightly.

Postoperative Care

Bulky dressings over the operative areas are usually discouraged, because they are normally left in place for at least a week and are extremely uncomfortable in warm weather. Perspiration and blood that dry under the dressing create an obnoxious odor and provide an excellent culture medium. The dressings usually have to be soaked off, which also creates discomfort for the patient. The open technique or a thin layer of Telfa or N-Terface is much preferred by the patient, the family, and the surgeon. The patient is reminded of the importance of taking the antibiotic and antiviral therapy until the recommended course has been completed. Normally by the end of 7 or 8 days the patient can apply makeup and be comfortable going out in public. It is stressed to the patient that sunblock must be worn as the first application on the skin each morning before makeup is applied or before leaving the house. If the patient has a lot of red in the skin, this redness will persist for a longer period than in Fitzpatrick type III and IV patients. A green base makeup applied to the red skin will neutralize the color, and then a light layer of natural makeup can be applied. The patient must be careful about being exposed to sun, especially when driving in a car, since glass is made of quartz, not lead, and does not provide any protection from UV radiation.

After a week or two, topical steroid creams can be used if there is marked redness or it appears that fibrosis is occurring that could produce scarring. Temovate cream 0.05% (clobetasol propionate), applied twice a day for 2 weeks and discontinued for a week, can be cycled until normal color returns. The patient must be warned that this is a potent steroid and should not be used continuously or not on the eyelids and only sparingly for the times indicated by the surgeon.

Problems and Complications

Hyperpigmentation and Hypopigmentation

With proper patient selection, and if the expected level of surgical skill has been executed, the results should be rewarding and predictable. Problems and complications, however, can occur with any procedure. Many of these have already been reviewed. Hyperpigmentation of the skin in patients with Fitzpatrick skin types V and VI certainly can be considered one of the least desirable results. Hypopigmentation can occur when very deep dermabrasion has been performed causing a decrease in the number of melanocytes.

Milia

As mentioned previously, approximately one third of the patients who undergo dermabrasion will develop milia, which appear as small white cysts over the surface of the treated area. They normally appear within 2 to 4 weeks after the procedure and will clear spontaneously in most patients. A buff puff or other mildly abrasive product can be applied to unroof these small cysts (see p. 483).

Residual Rhytids

Very deep lines are difficult to eradicate completely, and the patient should be advised preoperatively that filler materials might be indicated and recommended after they have completely healed. Attempting to remove every deep rhytid can produce scarring and surgical judgment is critical in knowing when to stop. This is especially true with postacne scarring, and it should be stressed to every patient undergoing treatment for postacne scarring that they may need a minimum of two to three procedures to achieve maximal improvement. All scars will never be eradicated and some patients will never be completely satisfied.

Scarring

If linear scarring occurs, this is usually caused by inadvertent angling of the drum so that it causes skin gouging from the leading edge (see p. 486). If noted at surgery, several small sutures can be placed and healing will normally occur without noticeable defects. Hypertrophic scarring is more difficult to address and can be caused by an abrasion that is too deep or when infection has occurred postoperatively. Steroid injections may be helpful, especially early in the scar formation.

Infection

Infection is extremely rare because most patients receive perioperative antibiotics and antiviral medications (see p. 481). Patients with occlusive dressings can hide a smoldering infection, and for that reason I do not use them. Hyperpigmentation and hypopigmentation have been addressed, and the patient should be warned preoperatively that these conditions can occur and can be permanent.

Result

This 62-year-old woman presented with severe sun damage resulting from an active outdoor lifestyle. She requested improvement of the deep rhytids in the perioral area. She did not request any other corrections. A photograph 6 months after dermabrasion shows smooth skin with normal color. The patient was counseled regarding future sun exposure.

Concluding Thoughts

For a technique first described about 1500 BC, dermabrasion is still valid as an excellent ancillary treatment for facial rejuvenation. Most important changes have occurred within the past five decades. Dermabrasion is a safe and effective technique that produces predictable results when performed properly. Careful patient selection and a detailed informed consent, which includes the limitations of the procedure, are essential for achieving optimal results and ensuring patient satisfaction.

Clinical Caveats

The drum should always be moved toward the leading edge of the soft tissue.

The drum should not be angled and should be kept parallel to the skin to avoid skin gouging.

Antiviral and antibiotic coverage is required.

Patients should be instructed to avoid sun exposure following dermabrasion until normal skin color returns.

Patients with acne scars and deep wrinkles should be advised that a repeat dermabrasion procedure may be needed.

Annotated Bibliography

Iverson PC. Surgical removal of traumatic tattoos of the face. *Plast Reconstr Surg* 2:427, 1947.

This is an excellent evaluation of the problem of herpes simplex infection following deepithelialization procedures. The beginning of the use of acyclovir drugs for treatment and prevention of this problem is also discussed.

Kromayer E. *Cosmetic Treatment of Skin Complaints*. New York: Oxford University Press, 1930 (English translation of the second German edition, 1929).

The author discusses development of the microdermabrasion technique, which is widely used today by many aestheticians and plastic surgeons on an outpatient basis for removing unwanted epithelium in a simple "lunchtime procedure."

Kurtin A. Corrective surgical planing of the skin. *Arch Dermatol Syph* 68:389-397, 1953.

To go back in time and review wound healing as described by one of the giants in plastic surgery is worthwhile, and this article is well worth reading and rereading.

Lawrence N, Mandy S, Yarborough J, et al. History of dermabrasion. *Dermatol Surg* 26:95-100, 2000.

The authors present a thorough historical review of dermabrasion from 1500 BC to the present. Included are all the advances in this technique, and for those who enjoy the history of procedures, it is one of the best resources and well worth reading.

CHAPTER 15

Chemical Peels

RICHARD H. BENSIMON, MICHELLE B. LOCKE,
FOAD NAHAI

The process of facial aging can be broadly divided into three categories: structural or gravitational changes, volume depletion, and textural or qualitative changes of the skin. Surgeons are experienced in and comfortable dealing with structural changes by means of a multitude of surgical procedures that receive the majority of attention in meetings and professional publications. This is understandable, because as surgeons we know how to perform surgery and it is within our capacity and experience to read about a new technique and successfully perform it. Correction of volume loss is a relatively new field, but many surgeons are increasingly becoming proficient in the use of alloplastic implants, autologous fat transfers, and injectable dermal fillers; these nonsurgical treatments are now an integral part of many plastic surgical practices.

The treatment of well-established rhytids, creases, and textural changes of the skin is altogether another matter. Surgeons are sometimes intimidated by this aspect of our specialty and tend to surrender their patients to aestheticians or use nonablative superficial techniques that are minimally invasive but may also be minimally effective. An all too common tactic is to simply ignore the problem. In doing so, surgeons are missing the opportunity to provide patients with a more complete rejuvenation and improve fundamental aspects of aging, such as the quality of the skin. Perioral rhytids can be more troubling to a patient than jowls or loose skin, and the very best face-lift results can be marred by deep creases around the mouth or forehead. The reality is that there must be a wounding into the dermis to improve deep wrinkles and etching of the skin, and at present this requires a more prolonged recovery period than that experienced after injectables are used. The goal is to find the best, most cost-effective approach that yields a result significant enough to warrant the recovery period and inconvenience to the patient.

Chemical peels represent an effective method for skin resurfacing to treat rhytids and other skin problems. Today physicians have a number of effective chemical peel options from which to choose; these offer the dermal wounding that is needed, with less morbidity and fewer adverse effects than with the agents that were available previously. Physicians can now plan the depth of peel depending on the patient's skin type, age, or clinical need. By choosing the appropriate resurfacing agent, solution concentration, and peel application, the surgeon can have precise control, thereby achieving treatment goals and avoiding possible problems with hypopigmentation.

Evolution of Treatment

Chemical peels were introduced to the United States in the early part of the twentieth century not by doctors, but by lay operators. The origin of the formulas used by these flamboyant individuals is unknown, but what is clear is that they involved the ingredients phenol and croton oil and that the clinical results were quite good. The early history of chemical peels has been elegantly chronicled by Gregory Hetter, and tracing this history is important to understanding and appreciating where we are today.

These early “lay peelers” used cumbersome “secret” formulas that involved dissolving phenol crystals and drops of the caustic croton oil. Over the years, as these individuals gained notoriety, the response of the medical community was to fight them rather than to learn from them. Eventually plastic surgeons took note, and finally Thomas Baker published a formula in 1961 that was easily reproduced by anyone. The ingredients were simple, and it was presumed that phenol was the peeling agent. In 1962 Dr. Baker altered the volumes of the formula for convenience, while keeping the 3 drops of croton oil unchanged. This effectively elevated the croton oil concentration to 2.1%, and thus he inadvertently altered the history of chemical peeling. This formula was very successful in improving severe wrinkles but also had the significant drawback of causing predictable and severe hypopigmentation. The peel gave dramatic results, but patients developed an unnatural porcelain or alabaster look that required them to permanently wear makeup. For older patients with pronounced wrinkling and light skin color this was a reasonable trade-off, but the peel was not done on younger patients or on darker skin. The peel was considered difficult to perform, and phenol developed the reputation of having an “all-or-none” phenomenon that was out of the surgeon’s control. The presumption was that phenol denatured the skin and created a barrier that prevented deeper penetration; a weaker concentration was thought to be dangerous, because it would peel deeper. It took a great deal of faith and courage to paint the solution on and hope for the best as the face densely frosted. Phenol also had the reputation of being cardiotoxic, requiring a deliberately slow application with strict cardiac monitoring. These beliefs became dogma, no matter how unsubstantiated, and were passed on from generation to generation of plastic surgeons. To this day, these presumptions are still mentioned in professional publications, and “phenol peels” have a negative connotation in lay books on cosmetic surgery. Although the results were quite remarkable, the factors discussed and the long and difficult recovery prevented this peel from gaining widespread acceptance.

The next development in chemical skin resurfacing was the popularization of trichloroacetic acid (TCA) peels by dermatologist Zein Obagi. TCA peels had been around for some time, but Obagi and Johnson’s work in the 1990s brought them to the attention of plastic surgeons. They popularized the concept of skin pretreatment,

as well as documenting and controlling the depth of TCA penetration. Obagi's role was controversial at the outset because of unseemly commercialization with "secret formulas" and very expensive training programs, but his book, *Obagi Skin Health Restoration and Rejuvenation*, remains an important contribution, especially for plastic surgeons less familiar with peels and skin anatomy and physiology.

TCA peels were an important addition in that Obagi showed histologically that different concentrations varied the depth of the peel and that the application technique was a major determinant of the depth reached. Lighter to medium peels were possible with a concentration of up to 25%, and medium to deeper peels occurred with 35% and 50% concentration for more pronounced rhytids. TCA therefore largely overtook phenol as the peeling agent of choice, because of the ability to control the depth of penetration and tailor the peel to the patient's skin type. Although higher concentrations engendered more serious complications, namely scarring, TCA peels at light- and medium-depth concentrations are viable and popular options when chemical peels are considered for facial resurfacing.

Another significant advance in peel resurfacing was introduced by Gregory Hetter in Las Vegas, Nevada. Interestingly, Nevada was a state in which aestheticians could perform weak phenol peels, and Hetter treated multiple patients who had had such peels. These patients had not achieved significant improvement, but more important, had not had any ill effects from the weaker phenol concentrations, directly contradicting what had been believed and taught about phenol peels for decades.

With this in mind, Hetter diluted the Baker formula in half and successfully performed peels on patients without the hypopigmentation that had attended the older peels. Clearly something different was at play, and Hetter devised a series of experiments to explain this phenomenon. Hetter performed peels on a series of patients with different combinations of ingredients of the Baker formula; he noted that phenol alone had scant effect and that adding croton oil to phenol at different concentrations led to deeper peels that were proportional to the concentration of the croton oil. An analysis of the classic Baker formula revealed that the concentration of croton oil was quite high at 2.1%, which was responsible for the results as well as the familiar drawbacks. Having convincingly shown that croton oil was the critical peeling agent, Hetter was free to alter the concentration of the ingredients as desired. He lowered the concentration of phenol and varied the concentration of croton oil, and in so doing, Hetter ushered in a new era in chemical peeling. The new formulas had the advantage of being clinically effective, similar to the classic Baker peel, without the troublesome complication of hypopigmentation. Having the freedom to alter the croton oil concentration as needed is a major advance that allows the peel to be performed superficially or deep, depending on the circumstance. This versatility makes the peel applicable to patients of all ages and skin types.

Having the ability to alter the croton oil concentrations has further ramifications. It is now possible to use croton oil concentrations weak enough so that the application technique becomes one of the important factors in determining the depth reached. The entire process is slowed down so that the surgeon can observe the skin changes and have the opportunity to stop at whatever depth is deemed appropriate. The all-or-none phenomenon seen with the Baker peel was simply that the croton oil concentration was so high that it immediately resulted in dense frosting. This consistently resulted in a peel deep enough to cause hypopigmentation.

Current peeling agents provide physicians with increased flexibility when treating wrinkles, creases, and skin pigmentation problems. It is now possible to use chemical peels to achieve the desired clinical results without reaching a depth that causes hypopigmentation. Another critical difference is that the surgeon can choose different concentrations on different areas of the face, depending on relative skin thickness. Many practitioners of the traditional peel were reluctant to apply a peel to the eyelids because of the fear of scarring, but now with the choice of a weak concentration of peeling solution, the delicate eyelid skin can be effectively improved with safety and predictability.

Pharmacology of Chemical Peeling Agents

Jessner's Solution

Jessner's solution is a standardized mixture of lactic acid, salicylic acid, and resorcinol (14% each) compounded in 95% ethanol. Alone, it causes a superficial epidermal peel. It may be an option for superficial peeling as an adjunctive treatment for acne. It can also be used as a pretreatment before a TCA peel, to enhance penetration of the TCA solution. It should be noted that salicylate toxicity (known as *salicylism*) can cause tinnitus, nausea, and headaches.

Trichloroacetic Acid

TCA (also known as trichloroethanoic acid; CCl_3COOH) is an analog of acetic acid in which the three hydrogen atoms of the methyl group have been replaced by chlorine atoms. TCA acts to dissolve keratin and coagulate surface proteins. This produces a frost as the salts precipitate. It is neutralized by contact with tissue fluids or topically applied saline solution for surface TCA. Lower concentrations (10% to 30% solutions) will produce a superficial epidermal peel. Higher concentrations (35% to 50%) penetrate into the superficial dermis, creating a medium-depth peel. Concentrations above 50% produce a deep peel, which is usually avoided, because this can result in scarring.

Phenol

Phenol, also known as *carbolic acid* or *hydroxybenzene* (C₆H₅OH), is an aromatic hydrocarbon derived from coal tar. The stock pharmacologic solution of phenol is known as *liquefied phenol USP*. This contains 88% phenol, which is the highest concentration that will stay in solution at room temperature; 100% phenol is a crystalline material at room temperature. Similar to TCA, phenol causes protein coagulation and produces a skin frost almost immediately. Liquefied phenol USP penetrates into the upper reticular dermis, causing a medium-depth peel. The Baker’s mixture is the most commonly used and reproducible formula; it is approximately a 50% (w/v) solution. Notably, less-concentrated solutions such as Baker’s mixture penetrate more deeply than higher concentrations, presumably because the more dilute mixture causes less keratocoagulation and more keratolysis, therefore permitting deeper penetration of the phenol.

Baker’s Phenol Mixture	
Liquefied phenol USP 88%	3 cc
Distilled or tap water	2 cc
Croton oil	3 drops
Septisol soap	8 drops

These ingredients do not combine easily. The liquid soap (Septisol) acts to saponify the solution. The solution must be stirred vigorously before application to ensure even mixture of the components.

Croton Oil

Croton oil is an extract of the seed of the plant *Croton tiglium*. Croton oil is the source of the organic compound phorbol. Internally, it is a purgative that causes severe diarrhea. Its action on the skin is related to free hydroxyl groups. It produces a caustic, exfoliating effect on the skin, even in low doses. As mentioned earlier, Hetter showed that croton oil was the essential peeling ingredient in the Baker’s mixture. Altering the concentration of croton oil directly alters the depth of the peel. Commonly used concentrations range from 0.1% to 0.8% croton oil solutions.

Indications and Contraindications

As with all aspects of plastic surgery, patient selection for chemical peels is vital to ensure consistent, reliable outcomes. Chemical peeling agents are ideal for treating wrinkled skin or skin with blotchy, irregular pigmentation. There is also some evidence to show that peeling the skin of patients with dysplastic epithelium or actinic keratoses may reduce or prevent the development of skin malignancy. The patient must understand that there is a difference between chemical resurfacing and face lifting. The chemical peel will improve rhytids and pigmentary changes but does not treat the gravitational and volumetric effects of aging.

Patient evaluation requires accurate assessment of skin color and type, skin thickness, and the amount of skin damage (such as rhytids, actinic damage, and pigmentary changes). Thicker, more sebaceous skin can tolerate deeper peeling than thin skin can. However, peeling is not a good treatment for large pores; pore size is rarely reduced by the peeling process, and in fact, large pores can become more noticeable and may seem larger after the peel.

Traditionally, the ideal patient has been considered to be one with thin to moderate skin, a fair complexion, blue eyes, fine to moderate rhytids, and actinically damaged skin. However, recent experience and increased knowledge have led to the understanding that chemical peels can be safely used in a broader spectrum of patients. Still, not everyone is a suitable candidate. All patients must be fully informed of the risks of hyperpigmentation and hypopigmentation, as well as the possibility of a line of demarcation at the margin of the peel. As usual with all plastic surgery, a thorough history, physical examination, and pertinent investigations should be performed before the procedure. These include a complete blood cell count, an electrolyte assay, urinalysis, and a blood urea nitrogen test for renal function.

Fitzpatrick Classification of Skin Type

The Fitzpatrick classification system can be a useful guide for evaluating a patient's skin type and response to sun exposure. Generally speaking, patients who burn and do not tan (type I) have a lower incidence of postpeel hyperpigmentation and are more prone to hypopigmentation. Conversely, patients with higher skin types (types V and VI) are more likely to develop postpeel hyperpigmentation. Fitzpatrick types III and IV tan easily; this implies that melanocyte proliferation (known as *rebound*) may occur after peeling. This tendency must be controlled with a prepeel skin care regimen. Therefore the greater the skin pigmentation, the longer and more intense the skin pretreatment regimen must be to control this rebound phenomenon.

Fitzpatrick Classification of Skin Type

Type	Color	Tanning Response
I	White	Always burns, never tans
II	White	Usually burns, tans less than average
III	White	Sometimes burns mildly, tans about average
IV	Brown	Rarely burns, tans more than average and with ease
V	Dark brown	Very rarely burns, tans very easily
VI	Black	Never burns, tans very easily

Skin type I

Skin type II

Skin type III

Skin type IV

Skin type V

Skin type VI

Glogau Classification of Photoaging

Glogau developed a classification system for photodamage based on the degree of skin wrinkling. This scale is commonly used to help determine skin type and thus treatment options.

Glogau Classification of Photoaging				
Group	Classification	Typical Age	Description	Skin Characteristics
I	Mild	28-35	No wrinkles	Early photoaging: mild pigment changes, no keratosis, minimal wrinkles; minimal or no makeup
II	Moderate	35-50	Wrinkles in motion	Early to moderate photoaging: early brown spots visible, keratosis palpable but not visible, parallel smile lines begin to appear; wears some foundation makeup
III	Advanced	50-65	Wrinkles at rest	Advanced photoaging: obvious discolorations, visible capillaries (telangiectasias), visible keratosis; always wears heavier foundation makeup
IV	Severe	60-75	Only wrinkles	Severe photoaging: yellow-gray skin color, prior skin malignancies, wrinkles throughout, no normal skin; cannot wear makeup because it cakes and cracks

Patients in Glogau II with moderate aging and pigment spots can be treated with a medium-depth peel. Medium-depth peels penetrate the papillary dermis and is effective for fine facial rhytids and pigmentary problems. Patients with Glogau III and IV skin have deeper rhytids and therefore require deeper peeling agents for effective results. Deep resurfacing agents such as phenol/croton oil may be more appropriate for these patients. Deep resurfacing is effective for fine and coarse rhytids, hyperpigmentation and epidermal dysplasia.

As discussed earlier, patients with darker skin types are less suitable for resurfacing. Other relative contraindications include a history of keloid scarring, cardiac abnormalities, and diabetes mellitus (unless the disease is well controlled and stable). Significant medical comorbidities such as hepatorenal disease or immunosuppression are contraindications to chemical peeling, as are abnormalities of collagen or elastin, such as Ehlers-Danlos syndrome, scleroderma, or collagen vascular diseases. As with

any plastic surgery, emotional or mental instability is a contraindication to chemical peeling. Peeling should be postponed until at least 1 year and perhaps longer after any treatment with oral isotretinoin (Roaccutane; Accutane) because of the increased risk of unpredictable scarring and keloid scar formation.

Pertinent Anatomy

Patients who request a chemical peel are commonly middle-aged and older women with aged or sun-damaged skin. Chronologic aging results from thinning of the epidermis and dermis along with loss of elasticity. Actinic changes are the photochemical effects of solar radiation damage. These changes manifest histologically as degeneration of the elastic network (elastosis), disorderly arrangement of the epidermis and collagen fibers, and flattening of the dermal-epidermal junction with loss of the rete ridges; thus the resulting dermis is more lax and less elastic. Melanocytes tend to increase in number but are less evenly distributed in the basal layer and contain variable amounts of melanin. Clinically, chronological and photoaging results in coarse, dry skin that shows wrinkles and tissue sagging.

Depth of Peeling

The comparative depth of penetration of peeling agents can be seen above. In superficial peels, the wounding extends to the stratum granulosum. Superficial peels therefore affect the epidermis only. Medium-depth peels extend into the papillary dermis, and deep peels extend into the mid-reticular dermis.

Histologic Changes With Chemical Peels

Biopsies taken 2 days after a Baker peel have shown necrosis of the epidermis. Depending on the depth of the peel, this necrosis can extend through the papillary dermis. There is a marked inflammatory response. A medium-depth peel, injuring the epidermis and papillary dermis, improves actinically damaged epidermis as well as producing neocollagen formation in the upper dermis. The wounded surface starts to reepithelialize from the follicular and eccrine duct epithelium. While the epidermis usually regenerates within 7 days, dermal regeneration is slower. New collagen formation begins within two weeks and may continue for up to a year. Obagi compared biopsies from 48 hours post-TCA peel with similar biopsies taken 6 weeks after a peel and found that medium-depth peels show a clearly defined new layer of fibrillar collagen and delicate elastic fibers in the upper reticular dermis. Deep peels showed that the neodermis formed almost the full thickness of the reticular layer. Therefore deeper peeling modalities produce a greater degree of neocollagen formation, which is spread deeper into the dermis. The neodermis shows horizontal, thin, compact bundles of collagen and a dense network of fine, elastic fibers. Melanocytes show fine, even distribution of melanin granules. However, melanin synthesis is impaired, and this can result in a generalized bleaching effect.

Prepeel Preparation

Regardless of the chemical peel to be used, adequate preparation of the patient is an important factor contributing to the success of the treatment. The patient must be motivated and understand the recovery period required. The reward is a dramatic long-term improvement in skin texture that is not easily replicated by any other modality. However, to achieve this, the patient must be prepared for the postpeel morbidity. The immediate postpeel phase, although not particularly long, can be trying for the patient; therefore it must be described realistically and in considerable detail. Detailed photographs of a representative patient's day-by-day recovery are shown to the patient and, if possible, to the patient's caregiver. Some patients will not tolerate the postpeel morbidity associated with medium to deep chemical peels. These patients can be treated with superficial peels, but they must understand that the clinical improvement will be less dramatic, and regular treatments may be required. Patients with coarse rhytids requiring deep resurfacing can gain a dramatic improvement but must be prepared for the significant postpeel recovery. It is worthwhile to have a prospective patient speak or, ideally, meet with patients who have had a similar peel. Seeing someone in person who has successfully gone through the process offers invaluable encouragement that although the recovery is difficult, it will be well worth it. The peel is well tolerated and the experience will be a positive one if the patient is well informed and the physician sets the proper tone.

Preparation of the skin before the peel is a means of preventing such complications as pigmentary changes. This is done by applying aggressive doses of tretinoin and hydroquinone 4%, as described below. Some companies offer a complete “set” of required products and a protocol for their use, such as the complete Obagi Nu-Derm system (Skin Specialists PC, Omaha, NE), which may be of value to practitioners. With an appropriate pretreatment regimen, the epidermis is stabilized, the dermis is stimulated to create more collagen, and the melanocytes are suppressed. The purpose is to regulate cell function and reduce the risk of postoperative pigment change. The skin is in essence “revved up” for the injury to come.

Preparation begins at least 2 weeks (ideally, 4 to 6 weeks) before the peel with applications of tretinoin 0.1%. Also known as Retin-A or Renova, this product is an acid form in vitamin A. It acts to decrease the cohesiveness of epidermal cells, which results in thinning of the stratum corneum. One inch (1 g) should be applied to the whole face once per day. The application should include the earlobes, tragus, and hairline, continue to 1 inch below the mandibular border, and up to 1 to 2 mm below the ciliary edge. The upper lids must be avoided, because application on this tissue could lead to irritation. The neck can be prepared in a similar fashion, less frequently, depending on whether irritation develops.

Hydroquinone 4% or other bleaching creams are used both preoperatively and postoperatively to reduce the risk of hyperpigmentation. Hydroquinone decreases melanin formation by inhibiting tyrosinase in melanocytes. Therefore it produces a reversible suppression and regulation of melanocytes. It is used for 2 weeks preoperatively (again, the ideal is 4 to 6 weeks), then again after the peel once the skin has resurfaced. Also, to prevent postinflammatory hyperpigmentation, glycolic acid 8% or phytic acid 2% is applied once daily to loosen desquamated cells in the stratum corneum and help accelerate exfoliation.

This process accelerates cellular turnover and results in erythematous, flaky skin; the patient must be prepared to accept this phase. Retinoid dermatitis is also common preoperatively. This can be lessened by decreasing the application of tretinoin to every other day for the first 1 to 2 weeks. The preparation should be stopped 4 or 5 days before the peel to allow the epidermis to settle.

The patient is instructed not to apply anything on the skin on the morning of the procedure.

This skin preparation regimen is certainly a nuisance, and there is controversy as to its absolute necessity. There are practitioners who successfully perform peels or laser resurfacing without it; greater experience and specific studies will be required before consensus is reached. Our experience has been that omitting or shortening the preparation has led to excessively long erythema.

Pretreatment Planning

Medications

Antiviral prophylaxis is routinely prescribed to all patients, regardless of whether they have a history of oral herpes. Valacyclovir hydrochloride 500 mg, 1 tablet two times a day, or the equivalent dose of acyclovir or famciclovir, is begun 3 days before the procedure and continued for 7 days after the peel. Although the postpeel phase is not particularly painful, narcotic pain medication is prescribed along with ibuprofen 800 mg 3 times daily. Steroids are administered intraoperatively, followed by a Medrol Dosepak begun the day after the peel. Sleep medication is prescribed and a mild sedative may be considered to help the patient cope with the inconvenience and isolation of the recovery period.

Solution Preparation

TCA

These solutions are generally prepared by a compounding pharmacist using appropriate weight-to-volume calculations (w/v) to achieve the correct percentages. As an example, a 35% TCA solution should be compounded by dissolving 35 g of anhydrous TCA crystals in a little distilled water, then more water should be added to bring the final volume to 100 ml. Dissolving 35 g TCA in 100 ml of distilled water is incorrect, as this will result in a more dilute solution than expected. The required variety of concentrations should be compounded by the pharmacist and not diluted from each other by the surgeon. If stored in acid-resistant plastic bottles, the stock solutions are stable for at least 2 years. Small volumes of each concentration can be poured from the stock bottles as required.

Using the correct concentration of TCA solution is vitally important. If the physician does not know a reliable compounding pharmacist, a national distributor can be used to ensure that the TCA mixture has been accurately prepared.

Croton Oil

Preparation of the acid peeling solutions is a critical step that ideally should be performed by the operating surgeon to ensure accuracy and consistency. The ingredients, including water, phenol, croton oil, and Septisol, are the same as in the classic Baker peel formula. They are inexpensive and can be obtained from compounding pharmacies or from Delasco (Council Bluffs, IA), a dermatologic supply company.

Traditional formulations used drops of croton oil which can be awkward to deal with and have the potential of dangerous variability especially when dealing with small volumes. The process is simplified significantly by delivering the croton oil in a

standardized stock solution consisting of USP phenol 88% 24 ml and croton oil 1 ml. This solution yields a reliably accurate concentration of 0.04 ml croton oil to 1 ml stock solution. This increased volume of ingredients allows easy measurement with standard syringes. As can be seen in the table below, the volumes of water and Septisol remain constant, and by varying the relative volumes of phenol and stock solution, different concentrations of croton oil are possible. As an example, to make a 0.8% croton oil solution, one would mix water 5.5 ml, Septisol 0.5 ml, and add USP phenol 88% 2 ml and stock solution 2 ml. The 2 ml of stock solution contains croton oil 0.08 ml. Because the total volume of the solution is 10 ml, the final concentration is 0.08 ml of croton oil in 10 ml total volume, or 0.8%. Weaker solutions such as 0.1% and 0.05% are very useful; to make these, one first makes 0.4% and 0.2% and these are further diluted, as noted in the table. The final concentration of phenol in all these formulas is 35% by volume. If a greater concentration of phenol is desired, the relative volume of the USP phenol 88% is increased and the volume of the water is decreased. *The stock solution, at 4% croton oil, should always be diluted—never applied full strength.*

Hetter Peel Formulas With a 35% Phenol Vehicle				
	Croton Oil			
	0.2%	0.4%	0.8%	1.2%
Water	5.5 ml	5.5 ml	5.5 ml	5.5 ml
Septisol	0.5 ml	0.5 ml	0.5 ml	0.5 ml
USP phenol 88%	3.5 ml	3.0 ml	2.0 ml	1.0 ml
Stock solution containing phenol and croton oil (see below)	0.5 ml	1.0 ml	2.0 ml	3.0 ml
TOTAL	10 ml	10 ml	10 ml	10 ml

0.1% = 1 ml of 0.4% + 1.2 ml phenol + 1.8 ml water.
0.05% = 1 ml of 0.2% + 1.2 ml phenol + 1.8 ml water.
Stock solution = 24 ml phenol + 1 ml croton oil (0.04 ml croton oil/1 ml stock solution or 4% croton oil).

A useful variation is to add olive oil to the solution to allow a smoother, more even application. For example, to make a 15% olive oil solution from the 10 ml formulas, one would include 1.5 ml of olive oil and decrease the water volume to 4 ml. In the weaker 4 ml total volume formulas, 0.6 ml of olive oil would be added and the water volume decreased to 1.2 ml.

Pretreatment Routine

Application of the peel is painful; therefore intravenous sedation or general anesthesia is usually necessary. Regardless, adequate blocking of pain is important to prevent excessive stimulation and allow the patient a pain-free emergence from anesthesia and a comfortable initial postpeel course. If the initial pain cycle is avoided, the entire recovery and general experience will be better. Some patients report mild tingling or burning on the first night, but they are usually pain free the following morning.

After sedation or general anesthesia, complete local sensory facial nerve blocks are performed with bupivacaine (Marcaine) with epinephrine. These include supraorbital, supratrochlear, infratrochlear, zygomaticotemporal, zygomaticofacial, infraorbital, dorsonasal, mental, and cervical nerve branches. Subcutaneous infiltration of dilute plain bupivacaine throughout the entire operative site is very useful. Color changes of the skin are important indicators of the depth reached; therefore epinephrine is not used in the superficial infiltration to prevent blanching. Intramuscular ketorolac tromethamine (Toradol) is administered as an adjunct to anesthesia if a concomitant operative procedure is not being performed. Steroidal agents are given intraoperatively, and a Medrol Dosepak is begun the next day.

Ophthalmic ointment and corneal protectors can be used during a peel to protect the eyes, but even when they are used, extreme caution around the eyes is imperative. If excessive ointment is used, any spilled or misplaced chemical may dissolve in the ointment and prevent immediate flushing out if it becomes necessary. Alternative measures include avoiding the use of ophthalmic ointment altogether or suturing the eyes shut.

The fear of cardiac toxicity has been historically associated with phenol peels, but rare reports of death are anecdotal, and it is impossible to implicate phenol toxicity rather than complications related to anesthesia. The occurrence of arrhythmias during peeling is well documented, and although rare, these are not clinically significant. Historically, traditional peels were performed with anesthesia or sedation but without local blocks. There is speculation that the catecholamine release from the intense stimulation caused by the high concentration of croton oil may have been the cause of the arrhythmias. With a lower concentration of phenol (35% versus 49%), a lower concentration of croton oil, and thorough local anesthesia of the face, cardiac complications have not been seen. Thomas Baker, who popularized the traditional peel, has stated that in his vast experience he has never encountered cardiac arrhythmias that required treatment. General recommendations include cardiac monitoring, adequate hydration, and peeling a full face in no less than 45 minutes. Following these precautions, we have encountered no cardiac complications in nearly 10 years of peel procedures.

TREATMENT

Application Routine

With the patient sedated and the nerves of the face well blocked, the skin is thoroughly cleaned and degreased with acetone or alcohol. This step is vital to allow even penetration of the peeling agent; a splotchy peel can occur as a result of uneven penetration if the skin still has residual oil or stratum corneum. Thereafter, the application process should be an orderly and nonintimidating one. The reason for this is that practitioners can choose an adequately weak concentration to slow down the process, depending on their preference and experience, to give ample time to judge the depth achieved. Furthermore, there are a number of factors at the surgeon's disposal (see below) that can be used to fine-tune the control of the application. In general, the different concentrations of solutions are placed in separate, easily identifiable bowls or cups. Materials for application are 2×2 gauze (preferably synthetic fiber, which is less abrasive) and cotton-tipped applicators.

Eyewash solution should also be kept in reach, in case an ophthalmic washout is required. For application, the gauze is folded twice, dipped into the solution, and carefully wrung out to avoid dripping. The solution is stirred before each application to ensure even mixing of the ingredients. An assistant helps dry the applying hand to prevent inadvertent application where it is not wanted. Consistent vigilance in this respect is imperative, especially in segmental peels, where errors will be obvious.

TCA Peel

Epidermal peels are performed with a 20% TCA solution, whereas medium-depth peels can be performed with more-concentrated solutions. We generally use a 30% to 35% solution for medium-depth peeling. Deeper peels are produced with 40% to 45% solutions. Concentrations higher than 50% are best avoided; at this high concentration, penetration into the dermis occurs rapidly and can be difficult to control.

The wet (not dripping) gauze sponge is used to apply the TCA solution in turn to each region to be treated. If the patient is awake, holding a fan close to the peeled area can help decrease the associated burning sensation. As the skin is treated, it develops a whitened color, known as a *frost*. There is a delay between the application of the solution and formation of the frost. In appropriately pretreated skin, the delay is approximately 60 seconds (45 to 120 seconds on average). Therefore, after each pass with the gauze, the physician should pause to observe the frosting before further application to the area. This process requires patience on the part of the physician but is essential to prevent undesirably deep peeling. Each region of the face is treated in turn until the desired depth of frosting is achieved, then attention is turned to the next region. We prefer to peel regions that require deeper penetration first (for example, the perioral region and the forehead) and regions to be peeled less deeply (such as the periorbital area) last.

Once the desired depth of peel has been achieved, ice-cold saline-soaked gauzes are placed on the peeled region. This relieves the burning sensation for the patient and helps to neutralize any remaining TCA solution on the skin surface to prevent further penetration. The gauzes warm up quickly and should be replaced or refreshed regularly with ice-cold saline solution. Removing the gauzes also allows the physician to assess the resolution of the frosting. Erythema appears after the frosting resolves, when serum in the tissue and vessels neutralizes the TCA and the coagulated proteins resolve. The time taken for the frosting to resolve and erythema to occur is directly related to the depth of the peel: frosting resolves more quickly with superficial peels than with deep peels. According to Obagi, superficial epidermal peels will resolve in less than 20 minutes. The frosting in medium-depth (papillary dermal) peels lasts up to 40 minutes. Deeper peels into the reticular dermis take longer to resolve, with frosting persisting for up to 60 minutes.

Factors That Influence the Depth of a TCA Peel

Low concentrations of TCA result in a more superficial peel. Higher concentrations peel more deeply. Peel depth is also related to the amount of acid and the preparation of the skin. Therefore depth can also be increased by applying more layers of

solution or by pretreating the skin with either Jessner’s solution or mechanical abrasion (for example, with a gauze sponge). This becomes particularly important if the patient has not completed the routine prepeel skin preparation regimen.

Assessing the Depth of a TCA Peel

Obagi has noted that the ability of the body to defend against the acid depends on the concentration and volume of acid applied, as well as on the thickness of the skin. Frost (or skin whitening) occurs as the skin proteins precipitate on application of TCA. The speed at which the frost develops varies with the concentration of the TCA used: dilute concentrations take 15 to 60 seconds to produce a frost, whereas higher concentrations may frost in less than 10 seconds. The precipitated protein disperses with time and therefore the frost disappears. Frosting of the skin is a helpful clinical sign to aid the surgeon in deciding when to end the peeling process, as the amount of frosting is related to the depth of the peel. Obagi grades frosting as level 1 through 3, as shown in the table.

Obagi Level of Frosting	
Obagi Level of Frosting	Clinical Relevance
1	Limited to the epidermal layer; a nonorganized, foggy or cloudy white frost on a pink (erythematous) background
2	Penetration to the papillary dermis; a regular, white-coated frosting with erythema still showing through
3	Penetration through the papillary dermis; a solid, intense white to yellow frosting, with no background erythema

In level 1, the peel penetrates the epidermal layer only and results in a combined pink and white frost that is disorganized or “cloudy.” Penetration into the papillary dermis produces a level 2 frost, which is a more uniform white frost, but with erythema still showing through. Penetration of the peel into the reticular dermis produces a solid white frost with no visible erythema; this is level 3. Deeper dermal penetration of the peel is undesirable; this produces skin with a grayish appearance and is associated with long-term scarring.

This patient is shown partway through the peeling process; she has also undergone an upper blepharoplasty followed by a full facial chemical peel with 30% TCA. Note the level 2 frosting of the forehead with visible erythema in the base, compared with dense level 3 frosting of the perioral region, where no erythema can be seen (*left*). At the end of the peeling process, there is level 1 irregular frosting of the nasal tip, regular level 2 frosting of the forehead, cheeks, and mental area, and level 3 frosting of the perioral regions (*right*).

Obagi also suggested the *epidermal sliding sign* to show when a TCA peel has penetrated the papillary dermis. At this level, the epidermis can slide over the firmer, immobile dermis, since the rete ridges have been disrupted. Skin firmness (turgor) can also be palpated. Untreated skin is soft to the touch, whereas a deeper peel results in firmer dermis caused by an increased amount of protein precipitation.

Recommendations for TCA Peels

The following are general recommendations of TCA concentrations in specific areas, but it is important to consider individual variations and to remember that concentration choice is only one factor influencing the depth of penetration of the peel. Regardless of concentration, it is imperative to always judge the depth of the peel as described in the previous section.

The whole face can be peeled with the same concentration of TCA, with depth varied by increasing the number of layers of solution applied, or by using varied concentrations of solution. In general, the author prefers to use a single concentration of solution, usually 30% to 35% TCA, to peel the entire face.

In general, the deepest peel should be performed in the perioral region. This is followed by the forehead and cheeks, with the lightest peels performed on the eyelids and earlobes. The perioral region has deeper rhytids and is peeled until a level 3 dense white frost is achieved.

Application

The 30% TCA is applied to the perioral region with a cotton-tipped applicator; this ensures accurate application of the solution into the perioral rhytids. The forehead and cheeks generally require a medium-depth peel, depending on the patient. Penetration into the papillary dermis is ideal; therefore frosting is carried to level 2. The solution is usually applied with gauze 2×2 squares to cover a large area evenly.

The solution is applied to the nose with a 2×2 gauze square on the dorsum and sidewalls, and cotton-tipped applicators are used to ensure penetration into the alar grooves. Because the eyelids have thin skin, the solution is carefully applied to this area with a cotton-tipped applicator. This is usually the last area of the face to which the solution is applied.

If the neck or décolleté region is to be treated, a lower concentration of TCA (such as 20%) should be used. This is because the skin in this area has fewer adnexal structures; therefore reepithelialization can be delayed with deeper peels. If the neck is not to be treated, the facial peel should be blended or feathered just below the mandibular angle by applying solution to this area very lightly.

After the peel is applied to the desired depth, iced saline-soaked gauze is placed across the patient's face to cool and relieve the burning. This is changed regularly to ensure the gauze stays cold and that the physician can review the resolution process. Once the frost starts to resolve, a thin layer of petrolatum-based occlusive ointment is applied across the peeled surface, and the patient is transferred to the recovery suite. Complete resolution of the frosting depends on the depth of the peel. The patient should be checked in the recovery suite, and the physician should note how long the resolution process takes. This is a good indication of the depth of the peel and aids the physician in developing judgment in the art of peeling.

The patient is shown 30 minutes after the peel, with resolution of the frosting.

Croton Oil Peel

Application

15-1 Croton oil peel

With the damp gauze in hand, the physician makes multiple passes, observing the color change of the skin to assess the frost formation. As the application progresses, the depth is gauged by the degree of frosting, which becomes progressively more dense and opaque. The speed at which the frost appears depends on the concentration used and the wetness of the gauze. With the typical concentrations described and use of a damp (not wet) gauze, the appearance of the frost is gradual and is seen in about 10 seconds. Unlike TCA peels, with a croton oil peel there is no need to wait several minutes to see the final depth. Once the acid solution is applied, there is no neutralizing agent and the effect is irreversible. The only recourse in this respect is that if a too-wet application is made, quickly blotting it will diminish the depth.

Factors That Influence the Depth of a Croton Oil Peel

The versatility and safety of the peel are based on the fact that there are a number of variables that determine the depth. Hetter's invaluable contribution was in demonstrating that the concentration of the croton oil is a key factor of the depth reached, and compared with older peels, is the demarcation between an excellent result and hypopigmentation. Regardless of the concentration used, the number of coats applied has an additive effect; therefore a weak concentration applied repeatedly can lead to deep involvement, even scarring. *The safety of a weak concentration is only relative and should never be taken for granted.*

As previously described, the croton oil concentrations are relatively weak, so the other main factor of the depth reached is the application technique, which is directly controlled by the surgeon. This is the fundamental difference between the modern croton oil peel and its predecessors. A damp sponge can be rubbed multiple times, variable pressures can be used, or the gauze can be wetter and fewer passes made. Theoretically, the same depth can be reached by using different techniques or even different concentrations.

The location on the face to which the peel solution is applied is significant because of the relative thickness and recuperative potential of the skin. For example, the perioral skin can sustain a deeper peel than the thinner, more delicate skin of the eyelids.

Assessing the Depth of a Croton Oil Peel

The key to success with these peels, as with any resurfacing technique, is choosing and safely reaching the appropriate endpoint. This depends on the degree of frosting, which is mainly a visual phenomenon, and therefore subjective and based on experience. Regardless of these apparent difficulties, photographs and available videos are very accurate references, and the process is not as daunting as it may initially appear. Anatomically, a superficial peel wounds all the structures of the epidermis. Such a peel may have an effect on pigmentary issues and be “refreshing,” but it cannot be expected to improve real wrinkles. Usually croton oil peels are deeper and affect change beyond the epidermis. A medium-depth peel goes to the papillary dermis. Deep peels go to the reticular dermis (upper to mid-dermis), and peeling to the lower reticular dermis can be problematic, leading to hypopigmentation and possibly scarring. The recovery, of course, is more involved with increased depth, but the harsh reality remains that to provide real change, there must be injury into the dermis.

The visual clues are a thin, transparent frost with a pinkish background denoting a peel to the papillary dermis. The pink hue is caused by the subdermal vascular plexus, still intact, showing through.

A solid, opaque, organized, even frost signifies that the upper to mid-reticular dermis has been reached.

A thick, gray-white sheet of frost with eventual red-brown overtones indicates that the mid-dermis has been reached—as deep as the peel should go. The red-brown overtones may take 15 minutes or more to become evident and are a reliable and accurate sign. Once a dense frost has been achieved, such as in the perioral area, it is worthwhile to wait to see whether the red-brown appears before considering further application.

Practitioners familiar with the different degrees of frosting with deeper TCA peels will have little difficulty transitioning to croton oil peels. *The important concept is that this is a gradual continuum that is slow enough, with the visual changes easily recognizable and predictable. An experienced practitioner can control the process, peeling slowly enough to recognize the various stages and is able to stop at the appropriate depth and go no deeper.*

Another indicator in evaluating the level of peel is epidermal sliding, which is seen when the peel reaches the level of the papillary dermis; the epidermis is separated from the underlying reticular dermis and slides as a thin, independent sheet. This sliding disappears when the reticular dermis is reached and the epidermis and dermis bond together, forming a single protein block. Epidermal sliding is most obvious in thin-skinned areas such as the eyelids and lateral forehead, as opposed to around the mouth. Epidermal sliding is a particularly telling indicator in the very thin eyelid skin, where the margin for error is small.

Defrosting, or loss of the frost, can also be used to assess or confirm the peel depth, although it is already after the fact.

Defrosting Times

Papillary dermis	5-10 min
Upper to mid-dermis	15-20 min
Mid- to lower dermis	20-30 min

Recommendations for Croton Oil Peels

The following are general recommendations for croton oil concentrations in specific areas, but it is important to consider individual variations and to remember that the choice of concentration is only one factor. Regardless of the concentration, it is im-

perative to always judge the depth of the peel, as described in the previous section. The perioral area (including the lower nose) is quite resilient and can be peeled with a strong concentration, such as 0.8%. This is extended beyond the chin onto the mental crease. Individual rhytids are stretched out to allow even penetration. The peel can be extended into the vermillion to improve lip wrinkles and gain beneficial lip eversion. The commissures heal well and can be peeled to a relatively deep level.

General Peel Recommendations*

Location	Croton Oil Concentration
Forehead, temporal area	0.2%-0.4%. The glabellar area can be peeled deeper than the lateral forehead and temporal area. Precise deeper peeling of individual lines is possible with a wetter cotton-tipped applicator and blotting dry as frost appears.
Perioral area (including lower nose)	Precise deeper peeling of individual lip lines is useful.
Cheeks, preauricular area	0.2%-0.4%. Deep peeling is rarely needed.
Eyelids	0.1% lower eyelids; 0.1% upper eyelids. Consider 0.05% in upper lids, especially below the tarsal fold.
Neck	0.1%. This is light peeling for blending of color, not for improvement of wrinkles.

*Predictable problem areas that require careful attention include the temporal area, immediate preauricular area, geniomandibular area, and the medial upper lid where it abuts the nasal skin. These are general recommendations. The key to the peel is to always judge the depth by the visual clues described, whatever technique or concentration is used. There is only relative safety in using a weaker concentration, and similar depths can be reached by the use of different techniques, even different concentrations.

The cheeks and forehead are peeled with 0.4% concentration. The glabellar area and central forehead are relatively thick and can be peeled to the mid-dermis (solid white frost). The lateral forehead and temporal area are more delicate and peeling to the papillary dermis is usually more appropriate (a white frost will appear, with a pinkish background). The peel can be safely extended to the hairline and brows to avoid lines of demarcation. Deep peeling of the cheeks is not often needed. Caution should be exercised in the preauricular area and geniomandibular groove.

The eyelids are peeled with 0.1%, and 0.05% is a consideration for the upper lids. In the lower lids, the peel is extended close to the ciliary margin. The peel is applied with a cotton-tipped applicator, and as in other areas, the relative dampness and number of passes affect the depth of the peel. The thin eyelid skin responds well and in a predictable way to these weak concentrations. Epidermal sliding and an even white frost are easily recognizable and reliable findings that denote the proper depth. If there is obvious redundancy of skin in the upper lid, the peel can be safely extended below the tarsal fold, possibly with a concentration of 0.05%.

The peel is extended onto the neck using 0.1% (or weaker) with light, wispy strokes, because this skin is thin and does not heal as well as the face. The endpoint is a light, scattered frost that is not at all organized. The neck skin is too thin to withstand a peel deep enough to improve wrinkles; doing so will result in hypopigmentation and quite possibly scarring. The purpose of the neck peel is to prevent the obvious demarcation that is commonly seen with laser resurfacing and deeper peels.

Precise deeper peeling of individual rhytids without affecting surrounding areas is a great advantage, especially in the perioral area and chin. This is done with a wetter cotton-tipped applicator, painting the individual line and then quickly drying it as a dense frost appears. This is very useful in troublesome radial lip lines. More precise application, as in the crow's-feet, can be done with the splintered wooden end

of the applicator. Focal repeeling of persistent rhytids is easy to do with the patient under local anesthesia. Repeat peeling either in part or whole has an additive effect. If peeling appears to be uneven or if there is a sharp demarcation between areas peeled with different concentrations, a weak concentration such as 0.2% or 0.1% is used to blend these sections.

The best way to learn these peels is to gain experience, but this must be done safely. Like any difficult procedure worth performing, whether a deep SMAS dissection or a TRAM flap, diligent study and attention to details are required. It is always worthwhile to watch another surgeon perform a peel, but this may be impractical. Good color photographs in publications and available videos are valuable to familiarize oneself with the visual aspects of the frost. One approach is to purposely plan on a lighter peel using a maximum concentration of 0.4% with the thought of performing a repeat peel should it become necessary. Thus the surgeon gains experience mixing and handling the solutions and visualizing the appearance of frost after application. It is never wrong to underpeel, and once this threshold is crossed, it is not difficult to progress to full-fledged peels.

Variation of Chemical Peels

Segmental peels are possible with any resurfacing agent but carry the risk of a mismatch in coloration; therefore good judgment must be exercised. Skin with widespread solar damage carries a risk of demarcation, so a full-face peel is preferable. Segmental perioral peels can be done, peeling to a medium depth at most. The color takes 8 to 10 weeks to blend adequately and the patient can manage color differences in the meantime with makeup.

In selected individuals with isolated upper lip lines, peeling of the mustache area can produce excellent results.

The skin of the lower eyelid responds very well to chemical peeling. When peeled to the appropriate depth, the thin eyelid skin contained within the borders of the orbital rim is very forgiving. Healing is well tolerated and easily camouflaged with makeup or glasses, making this an excellent location for segmental peeling. However, we would add a note of caution when treating this area: very low concentrations of peeling agents should be used. With croton oil peels we limit the concentration to 0.1%, and with TCA we limit the concentration to 20% or a very light pass with 30%.

Considerable improvement was achieved after a segmental peel in this 42-year-old man, whose wrinkled lower eyelid skin was incongruent with his otherwise youthful looks.

A major advantage of the lower eyelid peel is that it can easily be done under local anesthesia and in a gradual fashion. If a patient requests a procedure with a quicker recovery, a lighter peel can be done and repeated in the future with additive effect. In a real sense, the lower eyelid can be peeled to the patient's satisfaction. Treatment of the lower lids is a good option for chemical peeling because of its safety and predictability; it is a good starting point for patients who are reluctant to begin with a full-face peel. Regardless of the technique chosen, the wise surgeon will avoid serious problems by accepting that wrinkles cannot be completely removed with a peel procedure.

A novel use of these procedures is to perform a lighter peel in younger individuals to improve early imperfections while providing an easier recovery. These peels successfully improve early wrinkling and solar damage, restoring a brightness or lucency to the skin that evokes a look of youth. The aim of peels is to keep up with aging; they can be an excellent adjunct to many facial procedures, except surgeries in which major skin flaps are elevated.

This 45-year-old woman exhibited generalized elastosis and etching of the chin. Considerable improvement without loss of pigment is seen at 1 year, and her results remain stable after 6 years. Other than the original Baker peel, no other modality has been able to claim this kind of longevity of results.

Posttreatment Care

Once the peel is completed, the patient is observed until all the frosting subsides. The peeled area is then covered with an occlusive dressing, which acts as a mechanical barrier to enhance the results of the peel. This has been shown to increase the depth of phenol penetration. Previously, a waterproof mask of adhesive tape was commonly used for this purpose. However, this has to be removed usually 48 hours after the peel and is associated with increased patient discomfort, especially during removal. In addition, the physician is unable to view the peeled surface during the coverage period. More commonly today, a petrolatum-based occlusive dressing is used, such as Vaseline or Aquaphor. Alternatively, one tube of Polysporin (Pfizer) and one tube of lidocaine jelly can be mixed together and briskly beaten into an even emulsification. This antibiotic/anesthetic cream can then be applied over all the peeled areas to provide analgesia as well as occlusive coverage. The remainder of the mixture can be placed in a container and given to the patient for use at home.

The purpose of the petrolatum-based dressing is to moisturize the peeled skin to prevent crusting and provide analgesia. An advantage to this approach is that the wound is always in view for evaluation, and it is less painful for the patient. This regimen is inexpensive and effective; with more experience and more practitioners involved, other, better approaches may be developed.

The early phase of the recovery lasts 7 to 10 days as the skin gradually reepithelializes from the deeper layers upward. During this period, the wounded skin is moist and oozes serous fluid. Frequent application of the ointment is necessary to prevent drying and crusting. The patient is strongly admonished not to pick at or dislodge any crusts, because this may cause scarring. The surgeon must also exercise restraint in this respect.

Management of the postpeel phase begins before the peel with adequate information. Patients must fully understand what the experience will be like and how they will look. Showing photographs of the day-by-day recovery is valuable and ensures that the patient will be a willing participant based on accurate information. The early recovery can be challenging, but patients do well if they are well prepared.

Pretreatment

1 day after peel

Depending on the depth of the peel, the appearance on the first day can be impressive, and the patient may be almost unrecognizable. This 49-year-old woman had advanced wrinkling, sun damage, and smoker's lines. On day 1 after the peel (with anesthetic/antibiotic ointment applied), there is serous oozing and some blistering along the neck. Despite this appearance, most patients are not uncomfortable.

3 days after peel

5 days after peel

7 days after peel

4 weeks after peel

14 weeks after peel

On days 3 to 5 after the peel, there is resolution of the edema, and gradual reepithelialization is under way. On day 7, epithelialization is complete and marks the beginning of the erythema phase. Makeup may be worn at this time. At 4 weeks after the peel, the erythema is beginning to blend. At 14 weeks, the color has blended naturally without depigmentation. The next phase of the recovery is notable for erythema, which predictably lasts 8 to 12 weeks and is usually well tolerated with camouflage makeup. Intense erythema can be seen with deeper peels and can be improved with judicious short-term use of topical steroids.

Examination of the same patient's pretreatment views and her results 8 months later shows general tightening of the skin and notable improvement of deep wrinkling in the perioral and forehead areas. These photographs, taken with bounce flash, provide a more accurate rendition of her skin texture and demonstrate the generalized improvement particularly evident in the glabellar and periorbital areas.

Problems and Complications

Complications from croton oil peels are the same as with any other deep resurfacing technique. The main complications, scarring and hypopigmentation, are largely preventable by controlling the depth of peel. Delayed healing and thickening is evidence of peeling to the deep reticular dermis. This thickening or mild scarring can progress to a full scar but can be arrested and reversed by injecting triamcinolone acetonide 10 mg/ml and 5-fluorouracil (off-label use) in a ratio of 3:2 or 1:1.

Both hyperpigmentation and hypopigmentation can occur as blotchy areas or homogeneous abnormalities. They are less likely to occur in lighter-skinned patients. Hypopigmentation can occur if the peel penetrates deep enough. Alteration in pigmentation is more common in older patients; it seems to be related to decreased melanocyte synthetic function. For individuals with pronounced rhytids, adequate improvement may necessitate peeling to a depth that will result in hypopigmentation. The improvement is well worth it, and the porcelain look of the skin that was typical of formerly used peels is not seen.

Prevention of hyperpigmentation relies on the pretreatment skin care regimen, which acts to suppress the melanocytes. Transient hyperpigmentation may be seen during the recovery period; this responds well to prompt treatment with tretinoin and hydroquinone 4% over several weeks. Sun protection must be emphasized to the patient as an important factor in prevention of hyperpigmentation.

Infection in peeled skin can be bacterial, viral, or fungal. Bacterial infections tend to develop on postpeel days 2 to 5 and are usually caused by common pathogens such as *Staphylococcus aureus*, streptococci, or *Pseudomonas aeruginosa*. Bacterial infections are heralded by pain, fever, and purulence and are treated with topical wound care and appropriate antibiotics. Herpes simplex virus (HSV), the most common viral infection, is often the result of reactivation of a latent infection. It is usually heralded by dysesthesia or intense pruritus. Notably, as the epithelium is disrupted, the presentation of HSV is atypical, with erythematous erosions rather than vesicles being present. Treatment includes doubling the dose of oral antiviral therapy and adding a topical antiviral agent, which should be applied with a cotton-tipped applicator to prevent spreading the infection. A herpes outbreak can be very impressive but typically does not leave any permanent scars. Fungal infections most commonly occur with *Candida albicans* and present as painful ulcerations. Diagnosis is made with a potassium hydroxide (KOH) smear, and treatment is with oral antifungal agents such as fluconazole.

Hypertrophic scarring is perhaps the most feared complication with chemical peeling and one of the most difficult to treat. It most commonly occurs in areas of thinner skin such as around the lips or skin overlying bony prominences (for example, the malar region or chin). As with poor scarring in general, they often occur in areas where wound healing is delayed beyond 14 days. Treatment is generally nonsurgical, involving the application of steroid creams or topical silicone. If this therapy is ineffective, a course of triamcinolone steroid injections is recommended. However, given the difficulty in effectively treating postpeel scarring, prevention is undoubtedly the best cure through the judicious use of peeling agents, particularly while the physician is learning the techniques of chemical peeling.

Ectropion can result from excessive peeling of the lower lids. As with blepharoplasty, caution should be exercised in patients with lid laxity. Sequential lighter peeling and temporary suspension of the lower lid are helpful in preventing this complication. Mild tension in the lower lids is not uncommon and responds promptly to massage.

Milia are keratin-retaining cysts, which can be seen early or late in the healing process. They occur in up to 20% of patients 6 to 8 weeks after a deep peel. They sometimes respond to an increased intensity of the skin treatment regimen, specifically increased tretinoin. Failing that, gentle excision with a fine needle or electrocautery may be required.

Erythema usually resolves in 10 to 12 weeks after the peel procedure, but prolonged erythema (longer than 12 weeks) can be troublesome for the patient. Some physicians routinely use a steroid cream for the postpeel skin care regimen as a preventive measure. If not used already, steroid should be added into the regimen if erythema seems excessive and extended. Bleaching creams such as hydroquinone can also contribute to erythema and may need to be discontinued or an alternative pigmentation prevention treatment can be used, such as azelaic acid 20% cream.

Outcomes and Results

An invariable observation of the results obtained with croton oil peels is the overall qualitative improvement of the skin. The supposition is that there has been a fundamental change in the skin anatomy, which not only dramatically improves wrinkles but also significantly ameliorates the effects of sun damage. The skin reflects light differently and brightens the dull, ashen look of older, actinically damaged skin. This is the critical factor that has been missing in surgical facial rejuvenation.

A constant observation of the Baker peel is the long-lasting (if indeed not permanent) results. This has been substantiated by multiple histologic studies that have shown the deposition of a significant layer of collagen in the dermis after a peel procedure that is aligned in an orderly manner and is thought to be the mechanism for the effacement of wrinkles. This layer remains constant for years, even decades.

Since 2000, results with croton oil peels show remarkable improvement in deep wrinkles and actinic damage without depigmentation. These improvements are completely stable, and rather than showing diminishing results, the skin appears to improve with time.

This 47-year-old woman had brittle, sun-damaged skin and smoker's lines. Considerable qualitative improvement is seen after a croton oil peel with a stable result 4 years after treatment.

This 53-year-old woman is shown before a croton oil peel treatment and 4 years after the peel and a face lift. She also had an endoscopic brow lift and upper and lower blepharoplasties.

Pretreatment

1 year after peel

4 years after peel

Note the periorbital details in the same patient before treatment, with posttreatment improvement of texture after 1 year, and evidence of further improvement after 4 years.

Although not yet confirmed histologically, it is reasonable to expect that this stability is modulated by a similar deposition of collagen in the dermis, while not disrupting the function of the melanocytes. The fact that repeated peels produce additive effects suggests that there is more deposition of collagen each time. The skin looks younger because in essence, younger skin is being created.

Histologic studies have also shown eradication of actinic keratoses in deeply peeled skin. The anecdotal impression of experienced practitioners has been that individuals who have undergone peels do not develop facial basal cell cancer or squamous cell cancer. In a recent study in the dermatology literature, Hantash et al showed that laser resurfacing, fluorouracil, and 35% TCA peels were equally effective in keeping susceptible individuals free of nonmelanoma cancers for the studied 5-year period. The deeper croton oil peels are expected to have a similar or better effect, further expanding the benefits and utility of this approach.

The qualitative degradation of skin with time is obvious, and many patients consider textural changes to be equally or more important than structural changes. It could be argued that the qualitative and textural improvements achieved with a peel in this 61-year-old woman had greater impact than surgery could have.

There are many advanced surgical techniques to deal with gravitational and volume changes, but surgery can only minimally and indirectly improve textural issues and has no effect on the perioral area, where it is often needed most. This 59-year-old woman could certainly have benefited from a face lift, but her pronounced perioral lines would have been unaltered and a detriment to the results. The overall qualitative improvement, especially around the mouth, seen here 1 year after her peel, have had a greater impact than surgery would have.

The phrase *comprehensive facial rejuvenation* is frequently used, but unless these textural changes are dealt with as well, it is a mere platitude.

The preoperative view of a 75-year-old woman shows advanced structural and textural changes of aging. Neither surgery nor resurfacing alone could provide a complete result. The second image shows the patient at age 81, 6 years after a face lift and 1 year after a full-face peel. Croton oil peels provide a powerful and effective tool to complement surgery and make comprehensive facial rejuvenation a reality.

This 67-year-old woman had undergone two previous face lifts and overresection of the lower eyelids with rounding of the outer canthi. A corrective face lift and internal suspension of the orbicularis oculi muscles certainly improved the situation, but the subsequent peel was critical in completing the look of youth.

This patient had splotchy pigmentation from actinic exposure and upper lip rhytids. Note the improvement after a 35% TCA peel and upper lip dermabrasion.

This patient sought treatment for her fine facial wrinkles, particularly in the periorbital region. She is shown 5 months after a 35% TCA peel.

This patient was displeased with her periorbital rhytids and lower lid pigmentation. A 35% TCA peel was performed with good results.

Concluding Thoughts

Hetter's work and subsequent experience have greatly clarified the earlier issues regarding deep chemical peels, which are generally classified, possibly inaccurately, as phenol peels. A weaker concentration of phenol does not penetrate more deeply than a stronger one, refuting long-held beliefs. This allows greater latitude in the preparation of solutions. Croton oil has been identified as the critical peeling agent, and a high concentration of phenol is not necessary to obtain a desired peel. This knowledge also opens the door to investigate other solvents that may act as carriers of the croton oil and avoid the use of phenol altogether.

The "all-or-none" phenomenon attributed to the Baker peel, which was one of the main sources of intimidation for surgeons, is simply that the croton oil concentration was so high that the operator had little control over the application process. By lowering the concentration of croton oil, application technique and concentration choice now become the main factors that determine the depth of the peel. In this manner, the main complication of the traditional peel can be avoided while still providing the desired clinical result. The principal objections to deep "phenol" peels were misconceptions based on the experience of older peels that are now obsolete: hypopigmentation is largely avoidable by controlling the depth and by exercising rudimentary precautions, cardiac toxicity is simply not clinically seen.

Obagi's work with TCA in the 1990s was also an important addition to the field. Concentrations from 20% to 50% were found to be effective at producing superficial to medium and deeper peels, while largely avoiding the complications of scarring and hypopigmentation. With multiple concentrations of croton oil and TCA available as peeling agents, surgeons have significant control and specificity. This fact makes chemical peeling available to any age group and skin type. The possibility of doing weaker peels on younger patients with the thought of keeping up with aging

is an exciting prospect that has the potential of greatly expanding the patient base. Weaker concentrations of peeling agent can likewise be used to great advantage on delicate eyelid skin. Precise deeper peeling can be done on problem rhytids without adversely affecting other sectors of the face. The potential use of these peels in the prevention of basal cell and squamous cell carcinomas is a new frontier ripe for investigation.

The main drawback of modern chemical peels is the difficult recovery, but to date, there is no way to obtain comparable results without injuring the dermis and dealing with the recovery.

Clinical Caveats

Modern croton oil peels are a cost-effective means to achieve long-lasting results in facial resurfacing without hypopigmentation.

Skin pretreatment and patient education are important aspects of the process to decrease postpeel erythema and assist the patient in dealing with the postpeel recovery period.

The recognition of croton oil as the critical peeling agent allows the formulation of solutions with different croton oil concentrations.

Choice of concentration and control of the application technique allow the surgeon to choose the depth of peel desired.

The depth of peel is determined by the appearance and quality of frosting. This is a predictable and easily recognized phenomenon.

The above points give the surgeon great control and specificity. This allows treatment of a large range of ages and skin types.

The novice can approach the learning curve by peeling lighter with the thought of repeeling. This is a safe way to gain experience.

Repeated peels give additive effect. This is especially valuable in the effective treatment of lower eyelid skin.

Modern chemical peels are an important tool in the plastic surgeon's armamentarium. Surgery can deal with the gravitational and volume changes associated with aging, while chemical peels are an excellent adjunct to treat the textural and pigmentary skin changes that result from age and solar damage. By use a combined approach, the goal of facial rejuvenation can be attained.

Annotated Bibliography

CHAPTER 16

Lasers and Devices in Plastic Surgery

JASON N. POZNER, BARRY E. DiBERNARDO,
DAVID J. GOLDBERG

Cosmetic surgeons and other care specialists have expanded their practices to include many nonsurgical devices and procedures, and the technology associated with these procedures has become more diverse and complex. For example, liposuction has become extremely technical, with lasers and other energy devices used to precondition or tighten skin. Data from the American Society for Aesthetic Plastic Surgery reveal the changing nature of our practices. Comparisons of procedures performed in the United States in 1997 and 2008 (see below) demonstrate the increasing popularity of nonsurgical procedures. Cosmetic surgeons who do not offer these procedures may find themselves at a distinct disadvantage, because many patients who are seen in a practice for nonsurgical procedures tend to look to the same provider when more invasive surgical procedures are needed.

Ranking of Frequency of Cosmetic Procedures Performed in the United States*

Rank	1997	2009
1	Chemical peel	Neurotoxin injection
2	Collagen injection	Hyaluronic acid injection
3	Liposuction	Laser hair removal
4	Blepharoplasty	Microdermabrasion
5	Laser resurfacing	Chemical peel
6	Rhinoplasty	Laser resurfacing
7	Breast augmentation	Sclerotherapy
8	Face lift	Pulsed light
9	Hair transplantation	Breast augmentation
10	Forehead lift	Liposuction

*Data from the American Society for Aesthetic Plastic Surgery.

It has become difficult for physicians to differentiate manufacturers’ promotional claims from reality in determining which lasers and energy sources will be both beneficial for their patients as well as good long-term investments for their practice. The decision-making process is complex and depends on the scope of the practice, a willingness to accept risk, the number of physicians in the practice, the physical layout of the office, patient demographics, marketing, and other considerations.

There are many types of lasers/devices available for plastic surgery procedures, including skin resurfacing and skin tightening, tattoo placement, treatment of vascular lesions, hair removal, and treatment of cellulite.

The nature of the practice greatly influences the choice of technology. For instance, the addition of a device for treating cellulite probably does not make sense in a plastic surgeon's office in which the focus is primarily hand surgery, but such equipment may fit nicely in a body-contouring practice. Some of these devices are relatively esoteric, such as the excimer laser used to treat vitiligo, whereas others, such as pulsed light devices, will be used frequently. In this chapter we will review the devices used in our practices and discuss their applications and potential value. We will also assess newer devices and their potential for long-term use.

Laser Basics

The acronym *laser* stands for “light amplification for the stimulated emission of radiation”; in medical use this means a device that is composed of an energy source, a crystal or other laser medium, and a resonating tube. The medium may be a solid, liquid, or gas, and the laser is often named by this medium, such as carbon dioxide. The goal of the device is to create a photon that by definition is in the same phase, direction, wavelength, and frequency as the other photons emitted. The photon or laser beam created is monochromatic (a single wavelength). This is in contrast to an intense pulsed light device (discussed later), which is composed of many wavelengths. The wavelength determines the type of tissue interaction. Ideally, the laser beam is absorbed by the target tissue or chromophore, although the beam can transmit through the tissue, be scattered by the tissue, or be reflected by the tissue. The basis for medical laser use is *selective photothermolysis*, in which a specific wavelength of light is absorbed by a specific chromophore. For example, a vascular laser emits a beam that is absorbed by a blood vessel and heats the vessel until it is coagulated without damage to adjacent structures.

There are a few chromophores that are used for medical purposes: melanin, hemoglobin, and water. The corresponding wavelength peaks of absorption are shown for these chromophores.

Devices Used in Plastic Surgery and Dermatology

Pulsed Light

Pulsed light devices are powerful flashbulbs that emit a broad spectrum of light, usually from 400 to 1300 nm. These devices are different from lasers in that they have multiple wavelengths of emitted light. These devices either use different handpieces or cutoff filters that restrict light below a certain wavelength. There is usually a peak of energy at the wavelength just above the lower cutoff. For example, a 515 filter cuts off light below 515 nm and has a peak of energy just above this wavelength. These devices are used for many applications, such as pigment removal, vascular treatment, hair removal, skin tightening, and activating photodynamic agents. Excellent devices are available from various manufacturers. Specific differences between devices include disposable costs (how long the heads last), integrated cooling, programmability, and power. These devices are among the most versatile in a plastic surgery office and often are the first recommended for purchase.

Pigment Removal

Pulsed light treatment for facial pigment removal is often called a *fotofacial* or *photofacial*. The wavelengths used are in the low 500 to 550 nm range. As such, they are used on Fitzpatrick skin types 1 through 3 but may be used in Fitzpatrick type 4 skin types with lower fluences. Multiple treatments are usually recommended as a series of three or four sessions spaced 3 to 4 weeks apart. The pigmented areas appear darker immediately after treatment but fade thereafter. This technique is an excellent way to remove mottled photodamage in a nonablative fashion with minimal downtime.

This patient is shown before and 6 months after three pulsed light treatments of the face for pigment removal.

This woman required pulsed light treatment of the décolleté. She is shown before and 1 year after five treatments.

Vascular Lesions

Pulsed light treatment for removal of vascular lesions is for small vessel treatment and rosacea. Filters or handpieces used are near the vascular absorption peak in the high 585 to 595 nm range. These treatments work best on the face. Multiple handpieces or filters may be used in one treatment session to treat red and brown pigmentation. These devices may also be used for photodynamic therapy and will be discussed in that section.

This patient is shown before and 3 months after three vascular treatments at 4-week intervals.

Vascular Laser Devices

Historically, vascular lesions were one of the first targets for laser therapy. Lasers such as copper vapor (578 nm), krypton (568 nm), and argon dye (577 nm) were used and eventually abandoned because they produced unacceptable levels of scarring. The pulsed dye laser is still considered by most the benchmark for vascular lesion removal. Newer generations avoid the purpura produced by older devices. For portwine stains and hemangiomas, the pulsed dye laser is best, but as a device for a plastic surgery office, it probably will not be the most useful or cost-effective vascular laser. The 1064 nm laser and combination lasers of 532 nm/1064 nm and 585 nm/1064 nm are probably the most useful, because they can be used in all skin types and for hair removal as well.

Intense pulsed light devices are also very useful for vascular lesion treatment. However, their use is limited to patients who are not tan and with skin types 1 through 3 because of the melanin absorption. Their use is also limited to smaller vessels, whereas the 1064 nm devices can be used in vessels up to 2 mm in diameter.

Devices Used to Treat Vascular Lesions			
Device	Wavelength (nm)	Skin Types	Tan
Pulsed dye	585-595	1-3	No
KTP	532	1-3	No
Nd:YAG	1064	1-6	Yes
IPL/BBL	585+	1-3	No

BBL, Broadband light; *KTP*, potassium titanyl phosphate; *IPL*, intense pulsed light.

Facial vessel treatment is quite easy with any of the devices listed. Leg vein treatment is another story, and proper treatment usually requires multimodality treatment, such as venous mapping, evaluation of perforators and flow, sclerotherapy, and laser treatment for small vessels and for sclerotherapy “cleanup.”

This patient is shown before and immediately after vascular laser treatment to the nose with a 1064 nm laser.

Hair Removal Lasers and Devices

Laser hair removal is an extremely popular procedure: data from the American Society for Aesthetic Plastic Surgery list it as the second most frequently performed aesthetic procedure in 2008. There are many excellent devices by various manufacturers for hair removal.

Devices Used for Hair Removal

Device	Wavelength (nm)	Hair Color	Skin Type	Tan	Currently Used
Ruby	694	Dark	1-3	No	No
Alexandrite	755	Dark	1-3	No	Yes
Diode	810	Dark	1-6	Yes	Yes
Nd:YAG	1064	Dark	1-6	Yes	Yes
IPL/BBL	690+	Dark	1-3	No	Yes

Hair Basics

Human hair is currently thought to have stages of growth. These are the anagen (growth) phase, the catagen (regression) phase, and the telogen (resting) phase. In general, the anagen phase is variable in duration, the catagen phase usually lasts 3 weeks, and the telogen phase is approximately 3 months long, but there is some site-specific variation. The hair follicle has three regions—the lower segment, comprising the bulb and suprabulb; the middle segment (the isthmus); and the upper segment (the infundibulum). The bulb is made up of the hair matrix and dermal papilla. The dermal papilla is thought to be responsible for initiating and directing hair growth, whereas the hair matrix is the actively growing portion that gives rise to the hair shaft and root sheath.

For long-term hair removal, the laser or device must cause some damage to a growth section of the hair. The actual target is still somewhat controversial, but most researchers agree that the pluripotential cells of the bulge, dermal papilla, and hair matrix must be treated in the anagen phase to be effective. Melanin is the target for most hair removal lasers.

Treatment Considerations

Many variables affect laser or device hair removal: skin color, hair color, hair thickness, the area of the body treated, device type, wavelength, fluence used, spot size, pulse width, skin temperature and cooling, and treatment timing. Assessment of these variables is beyond the scope of this chapter; we encourage readers who are interested to read some of the books listed in the bibliography.

Devices

The many devices currently used for laser hair removal are grouped into lasers (specific wavelengths) and light devices (IPL/BBL: intense pulsed light/broad-based light—nonspecific wavelengths). Excellent devices are available from a number of manufacturers. The choice of laser/device depends somewhat on patient mix in one's practice (such as darker skin types or tan patients). The most popular devices are alexandrite lasers, diode lasers, Nd:YAG lasers, and IPL/BBL devices. As outlined in the table on p. 543, alexandrite and pulsed light devices should not be used on darker skin types or tanned patients. Diode lasers and Nd:YAG lasers may be used for these patients; Nd:YAG devices are considered safest for these skin types.

A patient who underwent treatment of a vascular lesion of the lip with a 1064 nm laser is shown 8 months after two treatments.

Treatment Protocols

The timing of treatment is a factor of anagen duration, which varies by age, season, anatomic region, sex, hormonal levels, and genetic predisposition. Some practitioners recommend a specific timing interval of 4 to 6 weeks, whereas others recommend a certain amount of regrowth before treatment.

Recommendations

Laser hair removal is a useful addition to a plastic surgery practice. We recommend a long pulse width Nd:YAG device for its usefulness in all skin types and a BBL/IPL device for its overall usability.

This patient is shown before and 3 months after six treatments with 1064 nm laser for hair removal.

Laser Skin Resurfacing

There are a wide variety of devices used for laser skin resurfacing. These are broadly classified into ablative and nonablative devices. Ablative lasers remove skin, whereas nonablative devices cause some degree of thermal damage to the epidermis or dermis without removing skin. These devices are further classified into fractional and full field devices.

Full Field and Fractional Resurfacing Devices

Name	Wavelength (nm)	Ablative	Nonablative	Full Field	Fractional
CO ₂	10,600	Yes	No	Yes	Yes
Erbium	2940	Yes	No	Yes	Yes
YSGG	2790	Yes	No	Yes	Yes
Thulium	1927	No	Yes	No	Yes
Er:Glass	1540	No	Yes	No	Yes
Nd:YAG	1440	No	Yes	No	Yes
Nd:YAG	1319	No	Yes	Yes	Yes
Nd:YAG	1064	No	Yes	Yes	No

YSGG, Yttrium-scandium-gallium-garnet.

Ablative Full Field Devices

Ablative laser resurfacing with the carbon dioxide laser was introduced in the mid-1990s and was responsible for creating significant interest in lasers among plastic surgeons and dermatologists. The CO₂ laser has a wavelength of 10,600 nm and a chromophore of water. There is laser absorption just above the ablation threshold, which vaporizes the tissue. Continuous mode devices were used initially, but too much thermal damage was created, which led to scarring. The continuous mode devices fared better as a cutting tool and are still in use today. A modification by one company (UltraPulse Laser; Lumenis Ltd., Yokneam, Israel) broke the continuous beam into short pulses, which caused tissue ablation with much less thermal damage. Originally the device was used with a nonscanning small spot handpiece, but the inaccuracy of the handheld probe led to overlapped pulses with excessive heat deposition through pulse stacking and/or else inadvertent deep resurfacing, both of which had the potential for delayed healing and scarring. The development of a computer pattern generator solved this problem by scanning the pulses sequentially onto the skin with a defined geometric pattern and spacing. A different approach was used by another manufacturer (SilkTouch and FeatherTouch lasers (Shurplan Lasers, Lon-

don, UK); they used an optomechanical flashscanner to scan a continuous laser beam in a spiral pattern. This allowed another method of creating a short exposure time by rapidly moving a continuous laser beam in a spiral, keeping the exposure or dwell time at any particular point below 1 millisecond. These devices led to excellent results in eradicating wrinkles and tightening lax tissue. The problem with this series of carbon dioxide lasers was the considerable downtime created for the patient and the permanent pigmentary problems that occasionally arose.

Erbium:YAG lasers (2940 nm) were introduced as a safer alternative for superficial resurfacing. Initially machines were low powered and lacked pattern generators. The second generation of systems had more power and were used instead of carbon dioxide lasers for deeper resurfacing. Complications were fewer, yet downtime appeared to be similar to that of carbon dioxide systems. Combination systems of carbon dioxide and erbium lasers were popular for a short time (Derma-K, Lumenis), with the beams being delivered either sequentially or simultaneously. Variable or long pulse erbium lasers (Sciton Inc., Palo Alto, CA) are popular today. These devices allow variation of pulse width in addition to energy per pulse, which allows control over the amount of residual thermal injury produced for a given amount of tissue removal. These variable pulse Er:YAG systems seem to produce skin tightening and wrinkle reduction similar to carbon dioxide lasers, with a much shorter period of erythema and much lower risk of hypopigmentation.

This woman is shown before and 1 year after full field erbium resurfacing.

This patient underwent full field erbium resurfacing and is shown 3 years later.

Yttrium-scandium-gallium-garnet crystal (YSGG) lasers (2790 nm) were introduced by Cutera (Brisbane, CA) to offer a device with a middle alternative to the CO₂ and erbium wavelengths. Erbium has the highest affinity for water in the absorption spectrum at 2940 nm. The laser was designed to create a wavelength with half the absorption that occurs at 2790 nm, the purpose of which is to create more heat driven down into the dermis for stimulation and remodeling. The mechanism of action is in three parts:

1. *Ablation*: Safe removal of a portion of the epidermis is achieved with a controlled amount of vaporization; 10 to 30 microns of epidermis are vaporized in this process.
2. *Coagulation*: Simultaneously, sufficient heat to produce coagulation is generated in the remaining epidermis. Depending on the energy selected, the coagulation region can vary from partial to full epidermal damage. This coagulation region creates a natural protective dressing on the skin that remains intact during the restorative process.
3. *Collagen remodeling*: Finally, residual heat in the dermis generates new collagen growth.

The YSGG laser can be operated as a horizontal ablative resurfacing unit or as a fractional device. Combination treatment called *fusion* can combine clinical situations of pigmentation, fine lines, and stimulation with the fractional effects of deeper dermal imperfection such as acne scarring, deep lines, and skin laxity.

This 74-year-old woman was treated for all of these conditions with a YSGG laser. Downtime is typically 3 to 5 days, and application of a thin ointment is the only required postprocedure care. She is shown before and 10 days after one treatment.

Plasma skin resurfacing used nitrogen plasma energy to coagulate a very controlled depth of skin. Healing times and results appeared to be similar to those with erbium devices. However, the company (Rhytec) that was manufacturing the plasma device is no longer in business.

Full field ablative resurfacing enjoyed an initial heyday from 1994 to 2001, but the associated prolonged healing times and hypopigmentation led to wariness of the technology. Consumers and physicians reversed direction, opting for procedures with minimal morbidity and downtime. This brought about the development of nonablative resurfacing devices.

Nonablative Devices

These devices were developed from the theory that full field ablative devices had two skin effects: removal of outer damaged layers and heating of the collagen/dermis to provoke a wound-healing response. The initial devices used were q-switched 1064 nm lasers. These extremely short pulsed lasers caused superficial dermal water heating and led to eradication of some fine lines and rhytids. However, there was some pinpoint bleeding, petechiae, and occasional purpura. Further development of

these devices led to use of other wavelengths with no epidermal injury through more water absorption and more dermal heating. The most popular of these devices were in the 1319 to 1320 nm range, although longer pulse width 1064 nm lasers and 1450 nm lasers were also used. These devices all caused some degree of dermal injury that led to a dermal wound-healing response. This then led to skin improvement with removal of some fine lines and wrinkles. The disadvantages of these devices are that results are inconsistent, and it takes months for results to occur.

Fractional Lasers

Fractional lasers have revolutionized laser resurfacing. *Fractional photothermolysis* refers to classes of devices that cause zones of epidermal and dermal thermal damage (nonablative fractional lasers) or that cause epidermal or dermal mini-holes or ablation channels (ablative fractional lasers). The adjacent areas are left free of damage, and healing occurs from areas deep and lateral to the damage.

The first fractional laser to be developed was the Fraxel laser (Solta, CA), a nonablative fractional device that used an erbium-doped fiber laser with a wavelength of 1550 nm. This device created microthermal zones (MTZ) between 125 and 250 per square centimeter. Multiple passes were performed, with a final density of 1000 to 3000 zones per square centimeter, a small fraction of the skin. Multiple sessions were used (usually three to five) spaced 2 to 4 weeks apart. Other manufacturers developed nonablative fractional lasers with different wavelengths (1319, 1440, and 1540 nm), energies, and spot sizes. The most recent ablative wavelength to be introduced is the thulium laser (1927 nm). This device may have some advantages, especially in treating actinic keratosis. Since different devices have different spot sizes, scanners, and depths of injury, it is difficult to compare devices. The easiest way to understand the degree of tissue injury is to understand depth of injury, width of thermal injury, and fraction of area treated.

These devices are in use today and are used to treat fine lines, deeper rhytids, photodamage, acne scarring, and melasma. Both facial and nonfacial areas can be treated. Downtime is related to the depth and density of the treated areas, but in general, downtime is minimal, with a mild bronzing of the skin for a day or so after treatment. These devices have enjoyed worldwide acceptance for all skin types; they produce minimal complications. The problem with treatment with nonablative fractional lasers is the relative lack of efficacy compared with full laser resurfacing. Currently these devices are used for mild photodamage and acne scarring, especially in darker-skinned individuals and areas off the face.

The development of fractional ablative lasers has increased the efficacy over nonablative fractional lasers. Three wavelengths are currently used for fractional ablative resurfacing: carbon dioxide, 10,600 nm; erbium, 2940 nm; and YSGG, 2790 nm (see the table on p. 546). The differences among these wavelengths are related to the differences in water absorption and in the resultant amount of thermal damage created.

A comparison of fractional technologies is shown, although not the variation in lateral thermal damage. YSGG (not illustrated) is similar to erbium long pulse. Also shown are the types of channels created. A newer development is the variable pulse width erbium fractional laser (Sciton). This device provides a short pulse followed by a longer pulse or a series of pulses to increase the amount of thermal damage. Studies of this device with maximum pulse duration or coagulation setting show histologic results similar to that with the carbon dioxide laser. Another new development is the introduction of grooves of ablated areas rather than the spots of fractional lasers.

As with fractional nonablative resurfacing, these devices are used to treat fine and deeper lines and rhytids, acne scars, dyschromias, and photodamage. These devices can create more skin tightening than nonablative fractional lasers. Comparison of devices and treatments is sometimes difficult because of treatment parameters, including spot size, depth of treatment, density of treatment, and thermal damage per spot. Treatments are usually performed with topical or regional anesthesia. Downtime depends on wavelength, depth, and density but in general is much less than for full field resurfacing.

This patient underwent one erbium fractional treatment of the forehead and is shown 3 months after the procedure.

Complications of ablative and nonablative fractional resurfacing are the same as one might get from full field resurfacing except for a much lower frequency. These include scarring, infections, prolonged erythema, and pigmentary changes, including hypopigmentation and hyperpigmentation. Scarring incidence is extremely low but is more common in nonfacial areas, especially when high energies (deep depth of treatment) and high densities are used. High densities with large amounts of thermal damage may approach full field resurfacing with a corresponding increase in complications. Infection rates appear to be low, most likely because of the widespread use of antiviral medications with treatment. Erythema is a product of inflammatory response, and duration of erythema increases with depth, density, and the degree of thermal damage.

The latest developments in laser resurfacing are combination treatments used to increase efficacy. One combination involves ablative and nonablative resurfacing. Early results of this combination show results that are superior to either modality used individually. Another combination is a light full field ablative treatment followed by a fractional ablative or nonablative treatment. The advantage of this approach is the full epidermal texture improvement seen. Downtime and efficacy depend on the depth of full field treatment and the depth and density of fractional treatment. Intense pulsed light treatment may also be added to these combination treatments to further correct pigmentation or vascularity.

Before treatment

2 days later

3 days later

1 week later

The progression of healing is shown following a combination superficial erbium and erbium fractional treatment.

This patient is shown before and after a fractional carbon dioxide treatment.

Skin Tightening

The concept of nonsurgical skin tightening is the holy grail of plastic surgery and dermatology. Many devices have been used for both facial and nonfacial skin tightening. The tightening is thought to result from dermal thermal damage, which causes release of heat shock proteins. The initial nonablative devices discussed previously did not cause enough injury to cause tightening. The next-generation devices currently in use are best described as being in one of three groups: radiofrequency, light-based, and ultrasound.

Radiofrequency devices used for skin tightening are based on radio waves. Various devices use different frequency waves and are measured in megahertz. The devices are either (1) bipolar, in which both electrodes are at the treatment site and charged particles are rotated between electrodes causing heat, or (2) unipolar or monopolar, in which the return electrode is distant. The depth of penetration with monopolar or unipolar devices is greater. Devices also differ in their power; some have far greater energy than others. These devices have been extensively studied. Initial protocols of one of the first to market devices, Thermage (Solta), caused deep tissue heating and undue complications, including burns and fat atrophy. Modifications and refinements to these systems have improved efficacy and decreased complications. The skin tightening in some cases is profound; in others it is virtually nonexistent. Current research is attempting to determine who are the best responders and why.

Primaeva, recently purchased by Syneron (Yokneam, Israel), has developed a skin-tightening technique that uses bipolar radiofrequency needles that actually pierce into the skin. Energy is delivered directly within the reticular dermis. With this tech-

nique, there is real-time feedback of tissue temperature and impedance. Energy is delivered in a fractional pattern, so healing is optimized. A local anesthetic is required.

A similar situation exists for light-based devices. These devices are long pulse width IPL devices. Different manufacturers have devices with different wavelengths. Light-based nonablative treatment has existed for years. The Titan (Cutera) uses a very long pulse, 6 seconds, to cause deep heating in the deep dermis. A tricyclic pulse of cooling, heating, and cooling safely deposits the energy at a wavelength range of 1100 to 1800 nm. Initially used for facial tightening, other applications include body areas such as the neck, arms, abdomen, and some newer gynecologic applications. SkinTyte (Sciton) has a wavelength from 800 to approximately 1400 nm. These devices have integrated cooling and long pulse widths in the seconds range. Their chromophore is water, and they heat up the dermis to induce collagen changes. As with the radiofrequency devices, responders are inconsistent, with excellent tightening being achieved in some and minimal tightening in others.

This patient is seen before and 1 year after three treatments with a light-based skin-tightening device.

These devices are used in patients with lax facial and body skin who have residual laxity after surgery or who will not or cannot undergo surgery. It is thought by some that the best responders are younger individuals, with less-photodamaged collagen.

The newest devices on the market are ultrasonic. The first to achieve FDA approval is by Ulthera (Mesa, AZ); this novel device has a diagnostic ultrasound unit to discern target depth, and treatment heads that deliver small ultrasonic thermal bursts to the previously measured area. The initial FDA approval is for brow elevation, but European experience suggests that tightening of the SMAS and platysma bands may produce face lift-like results.

This patient is seen before and 90 days after a single Ulthera treatment.

Concluding Thoughts

The modern practice of plastic surgery includes many nonsurgical aspects, including lasers and laserlike devices. Some of these may take the place of surgery, while others are complementary to surgical options. As progress continues, a day may come when a face lift is uncommon and facial tightening devices provide face lift–like results. The beauty of plastic surgery is that we can mold and adjust ourselves to accommodate technologic advances.

Clinical Caveats

Pulsed light devices may be used for treating pigmentary irregularities, vascular lesions, and hair removal in lighter skinned, nontanned patients.

Leg vein treatment requires multimodality therapy.

Many types of hair removal lasers and devices are available. Selection depends on the patient's skin type and tanning, and on surgeon preference.

Laser resurfacing can be performed in full field or fractional treatments.

Laser resurfacing can be performed with carbon dioxide, erbium, or YSGG devices.

Combination therapy is often used with laser devices.

Fractional devices may use laser, radiofrequency, or ultrasound technology.

Annotated Bibliography

Bass L. Rejuvenation of aging face using Fraxel laser treatment. *Aesthet Surg J* 25:307-309, 2005.

According to the author, Fraxel laser treatment produces the resurfacing effects of tissue removal, treats pigmentary changes, improves rhytids, and stimulates tissue remodeling. Compared with other classical approaches, it has the advantages of no recovery time, no open wound, few nonresponders, few complications, and the ability to be used in all skin types. Data confirm that improvement with this treatment is substantial but is not yet well defined quantitatively in comparison with laser resurfacing.

Review of pulsed light and lasers, including the pros and cons of lasers and IPLs: design, cost, and other practical concerns for a typical office-based practice.

Weinstein CW, Ramirez OM, Pozner JN. Carbon dioxide laser resurfacing complications and their prevention. *Aesthet Surg J* 17:216-225, 1997.

A good overall review of laser resurfacing complications. In a series of 1925 patients, undesirable outcomes occurred mainly in the authors' early experience. These could be attributed to poor preoperative evaluation, faulty technique, and suboptimal postoperative care: 537 cases were perceived as an adverse outcome; 461 had either normal sequelae or complications that were readily preventable with proper preoperative evaluation and improved postoperative care; only 10 were the result of poor technique. Energies need to be directed toward perioperative factors to achieve a better understanding of skin healing and prevention of possible complications.

Weiss RA, Weiss MA. Devices for nonablative photorejuvenation. In Goldman MP, ed. *Cutaneous and Cosmetic Laser Surgery*. Philadelphia: Elsevier, 2006.

This chapter provides a good overview of the subject by two experts in the field.

Weiss RA, Weiss MA, Beasley KL. Rejuvenation of photoaged skin: 5 years results with intense pulsed light of the face, neck, and chest. *Dermatol Surg* 28:1115-1119, 2002.

The authors investigated the long-term clinical results on the face, neck, and chest using filtered flashlamp IPL for treatment of photoaging changes of telangiectasias, dyspigmentation, and rough skin texture through a chart review of patients with skin types I through IV who were treated by IPL. They concluded that signs of photoaging can be improved by IPL with a long-lasting result. Minimal or no downtime with minimal adverse effects can be achieved, and lasting skin textural smoothing, although not easily quantified, is an additional benefit.

CHAPTER 17

Sclerotherapy and Laser Vein Treatment

GIRISH S. MUNAVALLI, SIRUNYA SILAPUNT,
ROBERT A. WEISS

Venous disease encompasses a wide spectrum of clinical manifestations, including asymptomatic spider veins on the legs; intermittently bulging branches of the greater saphenous vein that extend across the knee; and dull, achy pain in the posterior calf after prolonged standing. The science of treatment of venous disease, *phlebology*, has roots dating to 400 BC: the ancient Greeks recognized venous disease as an undesirable and unsightly condition. Procedures involving the use of instrumentation to traumatize veins were described by Hippocrates in the fourth century BC, and procedures such as vein stripping were routinely practiced in the years that followed.

Today venous disease still presents a formidable challenge to diagnose and treat; it affects 40% to 55% of the population, with common symptoms of leg pain, swelling, and skin changes. Venous insufficiency, which is caused by valvular incompetence in the deep or superficial venous system, is the most common form of venous disease. Deep venous insufficiency occurs when valves are damaged by thrombosis and is beyond the scope of this chapter. Superficial venous insufficiency occurs when high-pressure leakage develops between the deep and superficial systems or within the superficial system itself. This elevated venous pressure results in sequential failure of the venous valves in superficial veins. Venous insufficiency in this system allows venous blood to escape from its normal flow path and to flow in a retrograde direction down into an already congested leg. Over time, incompetent superficial veins acquire the typical dilated and tortuous appearance of varicosities. Furthermore, insufficiency can lead to chronic morbidity in the form of stasis dermatitis, lipodermatosclerosis, atrophie blanche, and ulcerative, edematous skin changes in the lower extremities.

Farther downstream, changes involving the smaller branching vessels, such as unsightly or symptomatic venulectasis and/or telangiectasias, are a major consequence of superficial venous valvular insufficiency. These entities occur in 29% to 41% of women and 6% to 15% of men in the United States. Although up to 53% of patients with leg telangiectasias have associated symptoms, the most common reason patients seek consultation is cosmetic.

In the upper extremity, the forearm and dorsal hand veins represent the equivalent of varicose veins of the lower extremities. Sun, gravity, and other environmental exposures subject the hands to unique combinations of physiologic and environmental stress. With the passage of time, the hands lose volume as a result of muscle atrophy, bone demineralization, and loss of adipose tissue. Elasticity is lost and skin texture dramatically changes. This process is accelerated by solar-induced damage, which results in wrinkled, dyschromic skin and prominent and tortuous varicosities of the superficial veins of the hand and forearms, such as the cephalic vein and the basilic vein.

Pretreatment Assessment

Lower Extremity

Careful patient assessment is essential for patients seeking amelioration of the symptoms of venous disease. Evaluation and treatment in the lower extremity should be directed in a systematic fashion toward the size and type of vessel, starting with the proximal, larger vessels and working down to the distal, smaller vessels. Vessel types classified in the superficial venous system (from largest size to smallest) include:

- The greater and lesser saphenous veins with their respective direct tributaries
- Nonsaphenous vein varicosities (often visibly bulging veins)
- Reticular or feeder veins (often bluish colored)
- Spider veins or telangiectasia (located just below the epidermis)

The majority of symptomatic lower extremity venous insufficiency is attributable to the superficial venous system and specifically includes reflux of the great saphenous vein. Reflux of the lesser saphenous vein accounts for approximately 5% of superficial venous disease, whereas reflux of the remaining division of the superficial system is called the *lateral subdermic venous system*. Younger patients, in their twenties and thirties, usually present with telangiectatic webs on the lateral thigh originating from reverse flow or reflux in the lateral venous system. When there is a family history of large varicose veins, reflux originating from the greater saphenous vein or lesser saphenous vein must be suspected. A duplex ultrasound study in patients who presented for “cosmetic” treatment of leg veins demonstrated a relatively high incidence of early associated axial or truncal reflux in the greater saphenous vein.

During an initial consultation, reflux in the greater saphenous vein is first suspected based on active symptoms elicited during a thorough history and physical examination. Often these patients have a strong family history of venous disease, especially the presence of varicose veins in immediate family members. Symptoms of venous disease are most often localized to the medial surface of the leg and exacerbated by prolonged standing, or during the premenstrual period in women, and are typically relieved by cold, ambulation, or rest with leg elevation or by wearing compression stockings. Characteristics of venous pain can include a dull ache, burning, heavy legs, throbbing, leg cramping, or pruritus that worsens at the end of the day. Generally speaking, abnormalities on physical examination of the lower extremities such as pain, bulging veins, or skin findings such as discoloration or ulceration located on the medial thigh and ankle correspond with the greater saphenous vein distribution, whereas those located on the posterior calf and lateral ankle correspond to the lesser saphenous vein distribution.

EVALUATION OF LOWER EXTREMITY VENOUS DISEASE

Select Conditions Precipitating Telangiectasia Formation

Hormonal Factors

- Pregnancy
- Estrogen therapy
- Topical corticosteroid preparations

Physical Factors

- Trauma (contusion, surgical incision, lacerations)
- Infection
- Radiation dermatitis
- Erythema ab igne (chronic thermal injury)
- Actinic neovascularization

Component of a Primary Cutaneous Disease

- Varicose veins
- Necrobiosis lipoidica diabetorum
- Capillaritis (progressive pigmentary purpura)

Unlike the symptomatology associated with reflux in the larger vessels, telangiectatic lesions more often present as a cosmetic concern. The term *telangiectasia* was first used in the early 1800s to describe a superficial vessel of the skin visible to the human eye. These typically measure 0.1 to 1 mm in diameter and can be either a distended arteriole or venule. A host of conditions can precipitate telangiectasia formation. Varicose veins most likely lead to the formation of telangiectasias through either associated venous hypertension with resulting angiogenesis or vascular dilation. These varicose veins may or may not be clinically evident at the time of telangiectasia presentation but should trigger the systematic proximal-to-distal vein evaluation of the affected extremity in efforts to unmask subclinical venous disease.

Pertinent Anatomy

Normal Venous Anatomy of the Lower Extremity

Knowledge of superficial venous anatomy and the location of important perforating vessels is fundamental to recognition of normal patterns of varicose veins.

The greater saphenous vein is of primary concern when treating venous problems in the lower extremity. The saphenous vein originates on the dorsum of the foot in the dorsal venous arch, passes anterior to the medial malleolus, progresses through the medial calf across the posteromedial aspect of the popliteal space, ascends in the medial thigh, and terminates in the femoral vein at the saphenofemoral junction. It dominates the anteromedial superficial drainage system. As the saphenous vein reaches its termination, it receives important tributaries medially and laterally. Duplex ultrasound examination may identify reflux in one or both of these vessels.

The anatomy of the greater saphenous vein is relatively constant. It is understood that this vein lies on the deep fascia of the leg and thigh, but it is less well recognized that it lies below or deep to the superficial fascia. Current descriptions of the anatomy of the lower extremity vasculature do not always make this distinction, yet this fact is crucial to understanding the development of varicosities.

In varicose venous anatomy, the important tributaries to the greater saphenous vein extending upward from below are the posterior arch vein (vein of Michelangelo), which receives the three Cockett's perforating veins (posterior tibial perforators); the anterior tributary vein to the saphenous system, which lies below the patella and collects blood from the anterior and lateral surface of the leg; and the posterior tributary vein, which also empties into the greater saphenous vein in the upper anteromedial calf. Other tributaries that may terminate high in the saphenous system near the groin are the posterior medial thigh vein and the anterior lateral thigh vein. Either or both of these veins may become the site of varicose clusters.

Less common in primary varicosities, and more important in recurrent varicose veins after treatment, are other tributaries in the greater saphenous vein as it terminates in the fossa ovalis. These include the superior external pudendal vein, the superior epigastric vein, and the superficial circumflex iliac vein.

Leg varicose veins could be the result of retrograde flow from pelvic vein varicosities from the connection of pelvic veins, the external pudendal vein, and the saphenofemoral junction. The findings of varicose veins of the medial groin, medial buttocks, and pubic area in patients with chronic pelvic pain should lead one to suspect pelvic congestion syndrome.

This 34-year-old woman presented with recurrent varicose veins of the left groin and thigh 2 years after she underwent endovenous laser ablation for left greater saphenous vein reflux. She reported feeling heaviness and intermittent pain of the left pelvic area and groin for several years; her symptoms worsened with prolonged standing and during menstruation. Physical examination revealed reticular veins and bulging varicose veins of the left medial groin in addition to a varicose vein of the left thigh.

Duplex ultrasound showed several dilated veins in the left groin that continued proximally to the pelvic area. Her MRI/MRV showed an enlarged left gonadal and pelvic vein. She was diagnosed with pelvic congestion syndrome and was treated, with no subsequent recurrence of varicose veins.

Posteriorly, the most important of the axial veins is the lesser saphenous vein. This vein originates on the lateral aspect of the foot in the dorsal venous arch and ascends virtually in the midline of the calf, between the bellies of the gastrocnemius muscle. Unlike the greater saphenous vein, the lesser saphenous vein may penetrate the deep fascia at any point from the middle third of the calf upward. This fact explains the segmental rather than total nature of reflux that is found in the lesser saphenous vein.

Important tributaries to the saphenous vein are variable in location or existence but may include the posterolateral tributary vein. Superiorly, this tributary may be associated with a lateral thigh vein called the *anterolateral superficial thigh vein*. Another important and frequently encountered vein is the vein of Giacomini, which connects the lesser and greater saphenous veins. It may originate from the lesser saphenous vein or from its thigh extension and ends in the greater saphenous vein or its posterior accessory.

The value of knowing the gross anatomy of the superficial veins of the lower extremity is that any one of the systems may be the site of the growth of clusters of varicosities.

Significant Perforating Veins

The perforating veins connect the superficial venous system to the deep venous system and penetrate the fascia. Any one of these veins, alone or in combination, may be the source of hydrodynamic forces of venous hypertension that produce superficial varicosities. It is the abnormally high pulses of hydrodynamic pressure transmitted through incompetent valves that affect relatively unsupported superficial veins. Such pulses of increased fluid force originate to some extent from increased abdominal pressure and to a greater extent from increased compartmental pressure during muscular contraction.

The best recognized connections between the superficial venous system and the deep venous system are the saphenofemoral and saphenopopliteal junctions. Incompetence of the check valves at their termination has been suggested as the cause of distal varicosities from gravitational reflux. This reverse flow is said to dilate veins in a progressive fashion, from proximal to distal.

Because it is frequently the site of the first varicose veins or the first reticular veins that become varicose, the Boyd perforating vein in the anteromedial calf now receives great attention by physicians who treat venous problems. Experience with the duplex scanner reveals that venous incompetence at this level may be isolated and may be the first reflux to appear. Such incompetence may be asymptomatic; however, when the incompetence is symptomatic, it produces aching pain, fatigue, and even a throbbing discomfort as mentioned previously. These symptoms can be relieved by firm local pressure. Progressing proximally from the Boyd communicating vein are the perforating veins in the distal third of the thigh. These veins are named for English surgeon Harold Dodd and may be found in any location along the saphenous pathway in the distal third of the thigh. The third important series of communicating veins, the Hunterian (mid thigh) perforators, are named for Scottish surgeon and anatomist John Hunter.

Recognizing the normal anatomy and the most common perforating vein sources of varicosities makes identification of patterns of varicosities relatively easy.

Telangiectatic Leg Veins

Telangiectatic leg veins may be described as venous spiders, spider veins, sunburst veins, starburst veins, venous plexuses, dilated venules, venous blemishes, dilated venules and venulectasias, superficial or minor varicosities, essential cutaneous telangiectasias, vanity veins, and cosmetic veins. All of these terms describe the type of telangiectatic networks that may cause physical symptoms of pain and discomfort. More than 50% of patients presenting for treatment of these “spider veins” express

aching associated with them. These symptomatic veins are best categorized as arborizing networks (according to the Redisch and Pelzer classification). They are actually combinations or networks of telangiectasias (0.1 to 1 mm) and venulectases (1 to 2 mm). Painful telangiectasias on the leg are usually grouped; they are rarely present as isolated telangiectatic vessels or spider angiomas with a central arteriole. More important, symptomatic telangiectasias and venulectases commonly are associated with slightly larger blue veins, which have been called “feeder” veins, reticular veins, or minor varicose veins. These small subdermal blue veins may be tributaries of the saphenous system. Reticular veins are most commonly part of a superficial venous system that is separate from either of the saphenous systems, originally described as the “lateral subdermic venous system” by Albanese et al.

To diagnose and treat painful telangiectasias in a logical way, a precise classification is helpful. This includes telangiectasias (type I), venulectases (type II), associated blue reticular veins (type III), and reflux from primary varicose veins (types IV and V).

A disturbance of normal venous physiology with back pressure and reverse flow or reflux through incompetent valves results in transmission of pressure through reticular veins into venules, causing their expansion into telangiectasias and venulectases.

Telangiectasias located on the anterior aspect of the thigh could occur as a consequence of reflux in the following vessels: anterolateral tributary of the greater saphenous vein, inguinal fold reticular veins, incompetent saphenofemoral junction, superficial axial branches of the greater saphenous vein, or anterior branches of the lateral subdermic venous system. Although painful telangiectasias and venulectases may appear anywhere on the leg, they are most likely to occur near the knee.

Revised Vessel Classification

This simplified classification eliminates the mixed telangiectasia/varicose category. Because most patients have a combination of multiple varicose vein types, a description of type I in association with type II or type III varicosities is simpler. Classifying varicose veins in this way facilitates a more straightforward treatment plan.

Type I	Telangiectasia, spider veins 0.1-1 mm diameter Usually red (rarely, may be cyanotic) Type IA – Telangiectatic matting – <0.2 mm diameter network, bright red
Type II	Venulectasia (usually protrudes above skin surface; distinguished from telangiectasia by deeper color and larger diameter) 1-2 mm diameter Violaceous, cyanotic
Type III	Reticular veins (“minor” varicose veins, “feeder” veins) 2-4 mm diameter Cyanotic to blue
Type IV	Nonsaphenous varicose veins (primary varicosity of saphenous tributary usually related to incompetent perforator) 3-8 mm diameter Blue to green
Type V	Saphenous varicose veins (varicosities associated with reflux at saphenofemoral or saphenopopliteal junction or major perforators of saphenous system causing enlargement of long or short saphenous vein) Usually >8 mm diameter Blue to bluish-green

Regions in which painful groups of telangiectasias and venulectases are most likely to occur are shown by the shaded areas above. Patients most often complain of focal burning, throbbing, and aching in these areas.

Upper Extremity

The veins of the upper extremities, primarily the cephalic and basilic veins, are analogous to the greater and lesser saphenous veins of the superficial venous system in the lower extremities. Because of the proximity of these veins to the radial and ulnar veins, they are commonly used as bypass routes for procedures such as arteriovenous shunts in patients with renal disease. Sclerotherapy of upper extremity veins is not commonly performed for several reasons. Because these veins are not subject to the same hydrostatic pressures as the lower extremity veins, valves in cephalic and basilic veins do not commonly exhibit reflux and associated symptomatology. These veins usually do not appear overly distended or tortuous, and varicosities/telangiectasias do not generally develop in the upper extremities. A noted exception occurs with upper extremity exercisers, such as weight lifters, who perform frequent Valsalva maneuvers during exercise. Prolonged increase in intrathoracic pressure will increase flow through upper extremity veins and can result in clinically noticeable vein distention. This is a normal physiologic response and not considered pathologic. In our experience, branches of the cephalic vein in the forearm and dorsal hand are the most common areas treated with sclerotherapy. Detailed upper extremity venous anatomy is beyond the scope of this chapter.

Treatment Options

Ideally, treatment for unwanted leg veins would be performed in one session, cause no pain, and be 100% effective in clearing vessels, with no associated side effects. Unfortunately, the variation in vessel size, flow, depth, and type preclude the possibility of a single effective treatment modality. However, there are a number of effective treatments that can produce excellent results, including conventional and duplex-guided sclerotherapy for the treatment of larger vessels and telangiectasias and laser treatment of reticular and spider veins.

Conventional (Visual) and Duplex-Guided Sclerotherapy

Conventional sclerotherapy is indicated for the elimination of unwanted reticular veins and telangiectasias. When leg veins are managed in a systematic approach, feeder vessels or larger varicose veins are first eliminated surgically, with radiofrequency or laser ablation, and sclerotherapy proceeds from largest to smallest vessels, with 80% to 90% of vessels responding to one or two treatments. As with endovenous ablation, sclerotherapy is performed in patients of all age groups, ranging from patients in their late twenties to early seventies. If treatment is initiated early in the course of the disease and with proper proximal-to-distal treatment techniques, patients can expect to achieve excellent results. Although hypertonic saline solution is the sclerosant most widely available and used in the United States, there are many others from which to choose that are less painful to inject and less ulcerogenic if extravasated. Vessel size and, to some extent, location are two of the most important factors to consider when choosing a sclerosant.

In expert hands, nearly any vessel can be treated with traditional sclerotherapy techniques. It is more difficult to treat larger vessels, vessels with a high-grade source of reflux, vessels with a complex pattern of reflux, and vessels that lie deeper beneath the surface of the skin. Failures can be caused by incorrect assumptions about the patterns of flow, incomplete understanding of the anatomy, or incorrect placement of the delivery catheter or needle.

Direct duplex ultrasound visualization offers an alternative to “blind” sclerotherapy that has one very important advantage—after a treatment under direct visualization, there can be no doubt that sclerosant has been delivered where it was intended and that all areas of reflux have been exposed to the sclerosing solution. An important secondary benefit is that observable spasm is a predictor of vessel closure.

Indications for Sclerosant Usage

Solution (effective concentrations)	Trade Names	Mechanism	Advantages	Disadvantages
<i>Reticular Veins</i>				
Polidocanol (0.5%-1%)*	Asclera	Detergent (emulsifier)	Always painless Cutaneous necrosis low Effective at low concentrations	Urticaria (immediate) at injection site Skin necrosis from painless arteriolar injection
Sodium tetradecyl sulfate (0.2%-0.5%)	Sotradecol	Detergent (emulsifier)	Painless intravascular Painful extravascular Strong for varicose veins Effective at low concentrations	Skin necrosis with extravasation of concentrations >0.25% Expensive Hyperpigmentation postsclerosis Dissolves rubber—must use latex-free syringes to avoid allergic response
Hypertonic saline solution (20%-23.4%)	None	Hyperosmolar	Low risk of allergic reaction Readily available Rapid action	Painful stinging and cramping Highly ulcerogenic—high risk for skin necrosis if extravasation occurs
Saline and dextrose (25% dextrose and 10% sodium chloride phenethyl alcohol)*	Sclerodex	Hyperosmolar	High viscosity—remains in treated veins Low risk of allergic reaction Low risk of necrosis	Too weak for larger varicosities Slight stinging One concentration only
<i>Telangiectasias</i>				
Polidocanol (0.25%-0.6%)*	Asclera	Detergent (emulsifier)	Always painless Cutaneous necrosis low Effective at low concentrations	Urticaria (immediate) at injection site Skin necrosis from painless arteriolar injection
Sodium tetradecyl sulfate (0.1%-0.5%)	Sotradecol, Fibroven, Thrombovar	Detergent (emulsifier)	Painless intravascular Painful extravascular Strong for varicose veins Effective at low concentrations	Skin necrosis with extravasation of concentrations >0.25% Expensive Hyperpigmentation postsclerosis Dissolves rubber—must use latex-free syringes to avoid allergic response
Hypertonic saline solution (11.7%-23.4%)	None	Hyperosmolar	Low risk of allergic reaction Readily available Rapid action	Painful stinging and cramping Highly ulcerogenic—high risk for skin necrosis if extravasation occurs
Saline and dextrose (25% dextrose and 10% sodium chloride phenethyl alcohol)	Sclerodex	Hyperosmolar	High viscosity—remains in treated veins Low risk of allergic reaction Low risk of necrosis	Too weak for larger varicosities Slight stinging One concentration only <i>Not FDA approved</i>
Glycerine (chromated glycerin 72% solution mixed 2:1 with 1% lidocaine with epinephrine 1:100,000)	None	Osmotic	Relatively painless Lower potential to cause hyperpigmentation Cutaneous necrosis low Lower potential to cause telangiectatic matting	Can cause hematuria at high volumes (>10 ml per treatment session) High viscosity Cannot be used with lidocaine- or epinephrine-sensitive patients <i>Off-label use in United States</i>

*Now FDA approved.

Common indications for injection with duplex ultrasound visualization include the following:

- Greater saphenous vein without junctional incompetence
- Lesser saphenous vein without junctional incompetence
- Truncal or tributary vessels with large failed perforating veins
- Varicosities with saphenofemoral incompetence
- Varicosities with saphenopopliteal incompetence
- Resistance to other techniques of sclerotherapy
- Nontruncal varicosities larger than 5 mm in diameter
- Venous component of arteriovenous malformations
- Varicosities eroding into soft tissues
- Vulvar or scrotal varices
- Varicosities with large open connections to the deep venous system

Although it is generally safe and effective, situations do arise in which sclerotherapy is contraindicated. Any patient with a medical history significant for deep venous thrombosis should be thoroughly evaluated with duplex examination of the deep and superficial venous systems before treatment. Patients with a history of arterial insufficiency or hypercoagulable states should not be considered candidates for treatment. Additionally, sclerotherapy should not be performed on patients who are pregnant, bedridden, or severely diabetic.

Laser Treatment of Reticular Vessels and Telangiectasias

Although sclerotherapy and ambulatory phlebectomy remain the mainstay of treatment of varicose and reticular veins, lasers certainly play a role in the treatment of lower extremity telangiectasias. Upper extremity or dorsal hand varicose veins are best treated with sclerotherapy. Lasers typically have no role in the treatment of upper extremity varicosities.

In general, treatment with lasers and light sources is more expensive, results are less predictable, responses are more variable, and the risk of side effects is at least as high as with sclerotherapy. Candidates suitable for laser or light source treatment are those who are needle phobic, have failed sclerotherapy, or have developed untoward side effects from sclerotherapy. Others suited for laser treatment are fair-skinned individuals who either have vessels smaller than the caliber of a 30-gauge needle or foot and ankle vessels that are notoriously difficult to treat with sclerotherapy.

Lasers are typically reserved for the smallest telangiectasias of the leg, but newer long-wavelength lasers can be useful for spider veins up to 2 mm in diameter.

Lasers have the greatest utility in vessels smaller than the diameter of a 30-gauge needle. Additionally, lasers are a good option for treating vessels that are resistant to sclerotherapy. There are instances in which laser and light source treatments should

be considered rather than superficial sclerotherapy, such as patients who are fearful of needles or who do not tolerate sclerotherapy, patients whose vessels fail to respond to sclerotherapy, and those who are prone to developing telangiectatic matting following sclerotherapy treatment. Additional carefully monitored controlled studies are essential to better define the role of each of the available lasers and light sources, and the optimal treatment parameters for leg telangiectasias.

Despite the fact that sclerotherapy has a long list of potential side effects, including pain, swelling, urticaria, systemic allergic reaction, hyperpigmentation, telangiectatic matting, skin necrosis, and phlebitis, it remains the treatment of choice for most leg veins less than 4 mm in diameter.

STS, Sodium tetradecyl sulfate.

Overview of Sclerotherapy Treatment Regimen

When sclerotherapy is planned to treat varicose disease, the first treatment session is considered a test treatment and is usually limited to one or two sites. The goals of this test are as follows:

- To observe the patient for any allergic reactions
- To determine the patient's ability to tolerate the burning or cramping of a hypertonic solution
- To judge the effectiveness of a particular concentration of sclerosing agent
- To observe any reactions to the tape used for compression

The patient returns 4 to 6 weeks later so the test site can be compared with pre-treatment photographs. At each follow-up session the patient is asked if the painful symptoms have decreased and if the appearance of the varicosities has improved. When the symptoms have resolved, the physician can be confident that the treatment has been successful, even before visual improvement is evident. Conversely, if visual improvement is noted but the symptoms have not resolved, the source of reflux has not been eliminated, and a recurrence in the treated area is highly likely.

The usual number of treatments is two to five per region, with a typical interval between treatments of 4 to 8 weeks. After a series of successful treatments, a rest period of 6 months is preferred to observe for second-generation vessels and to allow venous pressure to normalize. Reevaluation is done at 6 months if new or recurrent vessels appear.

Patient Education

Before treatment is initiated, the patient is asked to view a sclerotherapy consultation video that explains the pathophysiology of spider veins, treatment options, pre-operative and postoperative care, and the need for compression therapy among other issues. After the test treatment and before the next treatment session, the patient is instructed to eat beforehand to avoid a vasovagal response. Female patients are told not to shave their legs or use moisturizers on the day of treatment, to wear shorts during treatment sessions, and to bring support hose to the visit.

Compression therapy is very important to improve and maximize the results following sclerotherapy. External compression collapses and decreases blood flow in the treated veins, allowing maximal sclerosant effects on the vessel walls. To achieve adequate compression, it is recommended that patients use class I (20 to 30 mm Hg) compression stockings for at least 2 weeks.

It is not uncommon for patients to present for a treatment session and request that lasers be used in place of sclerotherapy. Patients must be counseled that lasers are a second-line treatment for spider and varicose veins. They are not as effective as conventional sclerotherapy in their current technologic state. Treatment with currently available lasers requires longer sessions, is generally more painful, and poses more risk of causing harm.

TECHNIQUE

Glycerin Sclerotherapy

Glycerin is usually supplied in 100% or 72% solutions, in the chromated form. Because glycerin injected at 100% is painful and too viscous, it is usually diluted 2:1 volume/volume with 1% lidocaine with 1:100,000 epinephrine. It acts as an osmotic corrosive agent, causing damage to the vessel wall directly, and works very well on vessels 0.5 mm or smaller. To minimize the risk of hematuria, the use of more than 10 ml of glycerin per treatment is not recommended.

Lateral Thigh Telangiectasias

This 35-year-old woman presented with concerns about a spider vein on her right thigh (*arrow*). The veins had appeared after the birth of her first child 4 years earlier and persisted without worsening.

A clustering of 0.5 to 0.8 mm bluish-colored telangiectasias was evident on the right anterior thigh. These vessels were associated with a 2 mm reticular vein, which was injected. These associated telangiectasias were not located in the typical distribution for the greater saphenous vein.

The patient underwent a test treatment with two different sclerosants: 72% glycerin solution (compounded by the University Compounding Pharmacy, San Diego, CA) and 0.1% sodium tetradecyl sulfate (STS) (Fibro vein; V.S. Ltd., Birmingham, England) and wore compression stockings, 20 to 30 mm Hg, for the next 2 weeks to ensure the best results.

Treatment

The patient returned for a full sclerotherapy session 4 weeks after the test treatment. The previously treated areas were evaluated and showed good resolution of vessels, without evidence of hyperpigmentation.

The patient was placed in the supine position on a surgical table with a sclerotherapy tray nearby. After wiping with isopropyl alcohol, a disposable 30-gauge needle connected to a 3 ml syringe and filled with 1 ml of the 72% glycerin solution was used to cannulate the vein. The needle was bent at a 30-degree angle to facilitate cannulation. The solution was slowly injected into several places in the vein.

Standard Sclerotherapy Tray Contents

Cotton balls, dry and soaked with 70% isopropyl alcohol
Protective nonsterile gloves
30-gauge disposable plastic-hub needles
Cotton balls or rolls for compression
Transpore or paper tape
Nitroglycerin paste for prolonged blanching
Clearly labeled sclerosing solutions in 3 ml disposable latex-free syringes

On withdrawal of the needle, immediate but transient blanching of the telangiectasias was noted. After treatment, mild erythema and urtication were noted along the course of the treated vessels.

Foamed Sodium Tetradecyl Sulfate Sclerotherapy

Foamed sclerosant is an alternative to traditional liquid sclerosant; it offers several advantages:

- Better displacement of the venous blood to allow intimate and prolonged contact with the vessel wall
- Ability to maintain its concentration more than liquid sclerosant, which is diluted by venous blood
- Ability to travel farther along the vessel than liquid sclerosant

Currently, foam sclerotherapy is an off-label use.

Anterolateral Tributaries of the Greater Saphenous Vein

Foamed sclerosant was used to treat this patient, who complained of a bulging varicose vein, approximately 7 mm, located on the lateral aspect of her right thigh. To evaluate her problem, duplex ultrasound evaluation was performed on the right greater saphenous vein, with emphasis on the saphenofemoral junction. This was found to be within normal limits; however, the anterolateral branch showed evidence of reflux along its course.

Treatment

The patient was placed in the supine position on a surgical table with a sclerotherapy tray nearby. A disposable 27-gauge needle connected to a 3 ml latex-free syringe was used to canalize the vessels.

After flashback was visualized, the sclerosant solution, 0.5 ml of 1.0% foamed STS, was slowly injected into the proximal varicosity.

On withdrawal of the needle, the areas treated were gently massaged in a proximal direction. This process was repeated distally along the course of the vein, approximately every 4 to 5 cm. The patient is shown after treatment.

Dorsal Hand Veins

A foamed sclerosant was also used for hand sclerotherapy in patients who have cosmetic problems on their enlarged dorsal hand veins.

Careful consideration during the medical examination includes any history of hand trauma, weakness, carpal tunnel syndrome, need for frequent intravenous medications, and foreseeable need to canalize hand veins. Consent must include the fact that the treated vein would no longer be usable in the future, in the event that it would be needed as a route for intravenous access. During the physical examination, the brachial and antecubital veins need to be identified, which could be accessible in the event of a future need for intravenous access.

Treatment

The patient is placed in the supine position, and the arm and forearm on the side to be treated should be placed along the bedside. A disposable 30-gauge needle connected to a 3 ml latex-free syringe is used to canalize the vessels. The sclerosant solution, 0.5% to 1.0% foamed STS, is commonly used for hand sclerotherapy. Alternatively, the newly FDA-approved sclerosant, 0.5% to 1.0% polidocanol (Asclera) can also be used, foamed or nonfoamed. The sclerosant should be injected slowly after confirming a flash of blood in the needle hub. Vein distention and mild blanching occurs while the foam is being injected.

This 49-year-old woman presented with cosmetic concerns about her hands. She thought they looked old and “worn down.” She inquired about any treatments that could revitalize the appearance of her hands. She was distressed about the dorsal hand veins, which were especially prominent and had become more noticeable over the past 5 years. On physical examination, a bluish superficial varicose vein of approximately 5 mm was noted on the dorsal aspect of the left hand.

One year later, marked reduction of dorsal hand veins is seen on the left hand compared with the untreated right hand.

Postoperative Care

The patient should elevate the treated hand immediately after injection to minimize dilution of the foam sclerosant with venous blood and to maximize the contact of the sclerosant with the vein walls. Compression wrapping or a gauntlet is placed on the treated hand while the entire upper extremity is still elevated. The patient is instructed to carefully monitor for any changes in sensation, temperature, color, and decreased motion in the fingers on the treated hand. If these symptoms occur, the patient should loosen the compression bandage; otherwise, it should be kept on overnight.

Duplex-Guided Foamed Sodium Tetradecyl Sulfate Sclerotherapy

Volar Wrist Arteriovenous Malformation

The deep and superficial venous systems of the upper extremities are analogous to those of the lower extremities. The deep venous system contains the majority of the blood volume at any given time. Perforators connect the two systems, just as they do in the lower extremities. Reflux of these perforators or in the superficial system itself can cause a systematic weakening of the superficial vessel walls with distention and pooling of blood. Congenital dysfunction in these systems predisposes to arteriovenous formation.

This 52-year-old man was seen for evaluation and treatment of a lifelong, intermittently tender, protruding mass on the volar aspect of his left wrist. He noted that the swelling and lumpiness had worsened with age and were associated with increased sweating, redness, and heat sensation on his left hand in comparison to the right hand. He had been evaluated 10 to 15 years earlier by radiologic examination and was found to have an arteriovenous malformation. An approximately 5 cm spongy, bluish-purple mass was noted on the flexor aspect of the left wrist, with extension to the thenar and hypothenar eminences. The lesion blanched slightly with pressure.

The patient underwent a duplex ultrasound examination of the venous tributaries of his left wrist, which revealed an incompetent, refluxing perforator communicating between the radial vein and the more superficial cephalic vein. Additionally, slow flow was noted in the cephalic venous malformation. Duplex examination did not identify any other communicating perforators or aberrant vascular structures. The patient was willing to undergo duplex-guided sclerotherapy for treatment of the reflux.

Treatment

Under duplex guidance, a solution of 0.1% foamed STS was slowly injected with a 27-gauge 1-inch needle after withdrawing slightly to visualize blood flashback in the needle hub. A total of 1.5 ml of foamed STS was injected during the first visit. Foamed STS was achieved using the Tessari technique, in which 1 ml of the sclerosant in a latex-free syringe was mixed with 2 cc of air in an empty syringe using a one-way stopcock. Foam position was verified with duplex as being confined to the superficial cephalic vein, with little to no foam traveling to the deeper radial vein. In addition, firm pressure was applied just distal to the injection site to better localize the sclerosant. Immediate blanching and slight spasm of the vessel was noted after treatment. The patient had no complaints of pain at the conclusion of the treatment.

At the follow-up visit 5 weeks later, the patient noted a mild decrease in the lesion size and was treated again with 1.5 ml of 0.5% STS, resulting in the improvement shown.

Postoperative Care

In the immediate postoperative period, the patient's arm was elevated and the wrist massaged from the proximal to distal direction. A compression dressing was placed on the area and secured with Coban wrap. The patient was told to remove this dressing the following day. No further care was needed.

Long-Pulse Laser Therapy

Long-pulse Nd:YAG 1064 nm lasers have been developed in an effort to target deep relatively large-caliber cutaneous vessels. The primary benefit of this wavelength is its capacity for relatively deep penetration to approximately 0.75 mm in human skin, allowing targeting of vessels in the middermis. The wavelength is well absorbed by water and hemoglobin, but not by melanin, thus allowing treatment even in deeply pigmented individuals. However, high energies must be used for adequate penetration in these individuals. Only with sufficient fluence and facilitation of heat dissipation can the posterior wall of a larger diameter (1 to 2 mm) vessel filled with deoxygenated hemoglobin be reached and heated.

The newer pulsed 1064 nm lasers have pulse durations between 1 and 200 msec and are capable of more than 350 J/cm² at small spot sizes. In general, treatment with long-pulse 1064 nm laser light is relatively painful and requires cooling and topical anesthesia. Large-caliber vessels greater than 0.5 mm in diameter respond best. Vessels up to 3 mm can be treated with long-pulse Nd:YAG lasers. Some of the effects of hydrostatic pressure may be addressed by treating these larger vessels, although the pain experienced by patients significantly increases beyond a 2 mm vessel. Recent data suggest that by using smaller spots and even higher fluences, even small vessels respond.

It is likely that the 1064 nm laser achieves its vasodestructive effects by penetrating deeply enough to cause complete, circumferential thermal damage to the vessel wall. For patient comfort and epidermal sparing, some type of cooling must be employed, whether in the form of contact cooling, cryogen cooling, or ice-cold gel.

Anterior Thigh Telangiectasias

This 41-year-old woman presented with a 5-year history of anterior right thigh telangiectatic vessels. She had long wished to be rid of the unsightly, asymptomatic veins but had an overriding fear of needles, which prevented her from seeking treatment.

She agreed to undergo a series of test pulses with the long-pulsed Nd:YAG 1064 nm laser (Laserscope Gemini) to a small segment of the veins. She underwent a duplex examination of the right greater saphenous vein and right saphenofemoral junction, which revealed no abnormalities. Duplex examination did reveal enlarged antero-superior branches of the lateral subdermic venous system. The patient was unwilling to undergo duplex-guided sclerotherapy for the reflux and instead opted for 1064 nm laser treatment of her spider veins. She was informed that the results of this treatment would likely not be permanent.

Treatment

Courtesy Girish S. Munavalli, MD

Before treatment

Immediately after treatment

10 minutes after treatment

1 week after treatment

A grouping of telangiectasias on the patient's thigh were selected and treated at a constant fluence of 120 J/cm^2 with a spot size of 2.5 mm and varying pulse durations from 10 to 40 msec. Ice-cold gel was applied to the skin before laser treatment. A pulse duration of 30 msec produced the best immediate contraction, as illustrated by handheld digital microscopy.

Postoperative Care

The patient requires minimal care in the postoperative period. He or she should be made aware of the potential for posttreatment hyperpigmentation, which results from the hemosiderin degradation products of blood trapped in the vessel during and after treatment. The larger the treated vessel, the more likely the chance that hyperpigmentation will occur. Most hyperpigmentation resolves spontaneously within 3 to 6 months.

Concluding Thoughts

Sclerotherapy is a safe, effective treatment for leg and hand varicosities. The surgeon must recognize various patterns of varicose veins, thoroughly understand the pertinent anatomy, be familiar with sclerosants and injection techniques, and the use of compression therapy; these are the key to successful treatment. Underlying superficial or deep venous insufficiency requires management before one attempts to treat clinically apparent reticular or spider veins to avoid failure of the sclerotherapy and potential complications.

Clinical Caveats

Sclerotherapy

Be aware of your body position; avoid neck and back strain.

Avoid halogen surgical lighting—indirect lighting is best.

Use magnification (1.5 to 33).

For smaller matting, use double-polarized light.

Apply alcohol to decrease white scale reflection.

Stretch the skin taut for easier cannulation.

Bend the needle 30 degrees.

Obtain 30-gauge disposable needles with a plastic hub (needles are available at www.air-tite.com); the needle should be changed frequently if it dulls.

Do not attempt to withdraw blood into the hub with vessels less than 0.55 mm in diameter; intravascular placement cannot be confirmed except by the smooth flow of solution.

Before solution is injected, producing a tiny air bubble (approximately the volume in the hub) may be helpful to clear the existing blood.

Inject very slowly, with little pressure, 0.1 to 0.3 ml at each site.

For immediate pressure, apply cotton balls and tape for 24 hours.

Advise the patient to wear compression hose (20 to 30 mm Hg) for 2 weeks after treatment.

Foam Sclerotherapy

Be aware of the anatomy and orientation of each individual patient.

Use latex-free syringes when using STS.

Produce a small bolus of air or foam preceding injection of the sclerosant when possible.

Draw venous blood (low pressure and darker) freely back into the syringe before injection.

Visualize the initial injection of foam or sclerosant.

Stop if distention or bulging around the vein occurs.

Stop if the patient complains of discomfort at the first moment of injection.

Note immediate vessel contraction as a treatment endpoint.

Duplex-Guided Sclerotherapy

Try to identify reticular veins, which may be difficult to clinically appreciate but feed smaller vessels; if they are identified, treat those first.

Draw venous blood (low pressure and darker) freely back into the syringe before injection.

Visualize the initial injection of several drops of foam or sclerosant.

Stop if distention around the vein is seen on ultrasound.

Stop if the patient complains of discomfort at the first moment of injection.

The proper endpoint is total contraction.

Foam resting in the vein is often seen on duplex imaging.

Long-Pulse Laser Therapy

Use 1064 nm laser for treatment of leg telangiectasias.

Always check that safety glasses are in use by all.

Target only superficial reticular and telangiectatic vessels.

Use long-pulse laser therapy for vessels larger than 0.5 mm.

If the vessel is 0.5 mm or larger, start with a modest fluence of 60 to 80 J/cm² at a pulse duration of 30 msec (given a 2.5 cm spot size) and gradually increase the fluence.

If the vessel is 0.5 mm or smaller, start with a pulse duration of 15 to 16 msec.

Have ice-cold gel on hand to decrease the sensation of pain and avoid epidermal injury.

Strongly avoid double-pulsing or pulse-stacking the laser at these settings; vessels can be re-treated after several minutes if the settings need to be modified.

After successful treatment, note the vessel contraction, perivessel erythema, and edema.

Annotated Bibliography

Bowes LE, Goldman MP. Sclerotherapy of reticular and telangiectatic veins of the face, hands, and chest. *Dermatol Surg* 28:46-51, 2002.

Prominent, tortuous veins of the face and hands may result from the process of aging and constitute a source of distress for many patients. Marked telangiectases of the chest and face are similarly distressing to some patients. In this article the authors discuss the safety and efficacy of sclerotherapy for telangiectatic veins of the face and chest, and varicose veins of the hands.

Cabrera J, Cabrera J Jr, Garcia-Olmedo MA, et al. Treatment of venous malformations with sclerosant in microfoam form. *Arch Dermatol* 139:1409-1416, 2003.

Treatment of congenital venous malformations poses a major clinical challenge. Surgery is difficult and frequently unsuccessful, radiologic intervention with embolization has an ill-defined role, and conventional sclerotherapy has little to offer. The authors evaluate the efficacy and safety of sclerosant in microfoam form for treating congenital venous malformations.

Duffy DM, Garcia C, Clark RE. The role of sclerotherapy in abnormal varicose hand veins. *Plast Reconstr Surg* 104:1474-1479, 1999.

Large, tortuous veins involving the dorsa of the hands often become more prominent with the passage of time and are a common source of patient dissatisfaction. This article evaluates the results of sclerotherapy for the management of unsightly varicose veins of the dorsum of the hand. Adverse events are also discussed.

Tessari L, Cavezzi A, Frullini A. Preliminary experience with a new sclerosing foam in the treatment of varicose veins. *Dermatol Surg* 27:58-60, 2001.

Recently a new method of using a foam sclerosing agent for the treatment of leg veins has been described. The authors present a pilot study of Tessari's technique for producing the sclerosing and its use in sclerotherapy of major and minor varicosities. The authors evaluate the safety and efficacy of different doses and concentrations of the drug, as well as different methods of preparing the foam. The results of this technique are also evaluated.

PART IV

HAIR TRANSPLANTATION

This page intentionally left blank

CHAPTER 18

Applied Anatomy in Hair Transplantation

ALFONSO BARRERA

Historically, hair has been a source of pride to humans and serves as a distinguishing feature that adorns as well as protects. It is also one of our most variable characteristics. Wide differences in color, density, texture, length, and style characterize different races and ethnic groups. Hairstyling and adornment have evolved throughout the ages. Today men as well as women place a premium on hair fashion and products to enhance their appearance. Considering its significance, it is easy to understand why hair loss often causes severe emotional distress and why people seek hair restoration.

For a surgeon performing hair transplantation, it is important to have a basic understanding of anatomy and aesthetics to obtain optimal results. The character and texture of hair vary, depending on its stage of development and location. *Lanugo* hair is the soft, fine, and usually clear, nonpigmented hair that covers the fetus and generally sheds around the eighth gestational month. *Vellus* hair is the fine, clear, almost invisible hair seen on the forehead. *Terminal* hair, which is coarse, long, and of variable pigment, characterizes the adult years. Subtypes of terminal hair are found on the scalp, eyebrows, upper lip, chin, axillas, chest, and pubis. Vellus hair may become terminal hair; for example, facial vellus hair in adolescents may develop into a beard, and terminal hair on the scalp may turn into vellus hair in male pattern baldness and androgenic alopecia in females.

In an embryo, the hair follicles originate from both ectoderm and mesoderm in the third gestational month and continue to develop over the next 3 months. Hair follicles develop from microscopic indentations of ectoderm, the outermost of the three embryonic tissue layers. These indentations meet and combine with small elevations of mesoderm, the middle layer of embryonic tissue. The cells that form the hair dermal papillae, the fibrous sheath of the follicle, the blood vessels, and the erector pili muscles originate from the mesoderm.

The cells that form the hair matrix and the melanocytes are of ectodermal origin. The melanocytes produce the color granules in the central, hollow core of the hair shaft that give hair its natural color. The cells from the matrix divide and are pushed upward; they are continuously replaced by new cells forming beneath them. Later, two buds are formed from special cells to create the sebaceous glands and the erector pili muscles.

As the matrix cells continue to be pushed up and outward and become dehydrated by an extrusion process, they form a tubular hair shaft of dead protein called *keratin*. This hollow tube is then filled with color granules (melanin) that give hair its natural color. As we age, the melanocytes cease functioning, resulting in gray or white hair.

The anatomy details of the hair follicles are clearly seen in these photos. The epidermis, dermis, and almost immediately deep to that a slight brown bulging structure can be seen. This corresponds to the sebaceous glands. The hair shaft continues deep to the hair bulb, surrounded by subcutaneous fatty tissue.

Histology

To accomplish natural, aesthetic results in hair transplantation, one must pay attention to many small details, starting with the important histologic features of hair follicles.

Epidermis, dermis, dermal appendages, and subcutaneous fatty tissue can be seen on vertical histologic sections of skin taken for skin biopsies or when checking tissue margins after excision of skin lesions.

Multiple follicular units of various sizes

Close-up view

Two-hair follicular unit

One-hair follicular unit

Transverse sections demonstrate that hair follicles grow in follicular units. In his landmark 1984 article, Headington described the *follicular unit* as including one to four terminal hairs, one vellus hair (rarely two), nine sebaceous glands, insertions of erector pili muscles, a perifollicular vascular plexus, a perifollicular neural network, and perifolliculum (a circumferential band of fine adventitial collagen that defines the unit). This suggests that a unit constitutes at least to some degree a physiologic entity.

Follicular Units

IDEAL HAIR GRAFTS

When planning hair transplantation, it is important to maintain the follicular units as intact as possible. As long as the surgeon uses grafts with no more than four hairs per graft, the appearance of clumpiness (the “plug” look) can be avoided altogether.

Two two-hair follicular units may be used together as one graft, or one one-hair follicular unit may be used with a two-hair follicular unit as one graft. In selected areas it may be desirable to use primarily one- or two-hair follicular units (*micrografts*), as in the front hairline. In other areas a mixture of one- or two-hair follicular units and three- or four-hair follicular units (*minigrafts*) are desirable. In yet other areas, such as behind the front hairline, three- or four-hair follicular units are ideal, because they provide more density.

Design of the Hairline

The design of the hairline or the area to be transplanted is crucial, the idea being to mimic nature as much as possible. The position of the front hairline is critical for a natural result; conservatism is in order. The goal is to achieve a mature hairline. The size and shape of the head vary from person to person, as does the position of a mature hairline. Generally, the midline of the new hairline is approximately 8 cm from a horizontal line immediately above the eyebrows. In some patients a slightly longer or shorter distance is appropriate, depending on the specific facial features, shape, and size of the head as well as the interrelationship and proportions of the face and skull.

Growth Cycle

There are three life cycle phases of hair growth. The living cells at the base of the hair follicle first show active, mitotic growth, eventually forming a compact column that extends toward the surface of the skin. A zone of keratinization then forms directly above the actively dividing cells. The living cells become dehydrated, eventually die, and are converted into a mass of keratin. The keratin filaments are finally cemented together by a matrix rich in cystine. The average rate of growth of scalp hair is approximately 0.35 mm/day or 1 cm/month. The dermal papilla, which is situated just under the actively dividing cells of the follicle, plays an important role in the regulatory control of the hair's growth cycle.

The first phase, *anagen*, is the active growing phase in which the follicular cells are actively multiplying and keratinizing. In a nonbalding scalp, approximately 90% of the hairs are in this phase, which lasts about 3 years. During the second phase, *catagen*, the base of the hair becomes keratinized, forming a club, and separates itself from the dermal papilla. It then moves toward the surface and is eventually connected to the dermal papilla only by a connective tissue strand. This phase lasts 2 to 3 weeks.

The third phase, *telogen*, is also known as the “resting phase.” During this phase the attachment at the base of the follicle becomes weaker until the hair finally sheds. During this period the follicle is inactive and hair growth ceases. This phase lasts 3 to 4 month—and commonly occurs after hair transplantation. For this reason, significant growth of the hair grafts is not seen until this phase is over. In addition, some of the native hair often goes into the catagen phase and then into the telogen phase from the insult of the surgery; this is called telogen effluvium.

Approximately 10% of hair follicles in a nonbalding scalp are in the telogen phase. When the rate of hair loss exceeds the rate of growth, thinning and eventually baldness develop.

Applied Anatomy

Male pattern baldness is a gradual conversion of hairs from the terminal (healthy, thick) to the vellus (clear, microscopic) state. In the most common type, male pattern baldness primarily affects the top of the head while the hair on the temporal and occipital areas is preserved. Hair loss in women, female androgenic alopecia, occurs less frequently and is more diffuse. In women, the front hairline is usually preserved. Both of these are naturally occurring and have primarily a genetic origin. This is a hereditary condition that appears to be controlled by a single, dominant, sex-linked autosomal gene. The expression of this gene is dependent on the level of circulating androgens. The initial signs of thinning clearly correlate with puberty in males, when the levels of androgens (testosterone) start to rise, gradually converting terminal hair into vellus hair. Initially this results in a receding hairline and, depending on the genetic features inherited, may progress until only a temporal and occipital fringe remains.

Testosterone secreted by the testes is the principal androgen circulating in plasma in men, whereas in women the adrenal steroids dehydroepiandrosterone sulfate, androstenediol sulfate, and 4-androstenedione are the most abundant proandrogens. A *proandrogen* is a 19-carbon steroid that is converted at the target tissue into active androgen. The enzymatic reduction of testosterone and the previously mentioned androgens in females by 5- α reductase into dihydrotestosterone is necessary for the induction of androgenic hair loss in both men and women.

Although genetic predisposition is the cause of most forms of hair loss, other sources of hair loss include (in order of frequency in my practice):

- Hair loss associated with aesthetic facial rejuvenation surgery, coronal and endoscopic forehead lifts, such as loss of sideburns, temporal hairline, and distortion of the retroauricular hairline

- Scalp and facial hair loss associated with burns or other traumatic injuries

Congenital abnormalities of the face or scalp, such as vascular malformations and melanotic nevi that require surgical excision
Postoncologic resections resulting from the excision of skin or scalp tumors

Surgeons must be equipped to restore sideburns, the temporal hairline, the retroauricular hairline, eyebrows, eyelashes, mustache, beard, and areas of the scalp. Many remedies have been described over the centuries to enhance and/or regrow hair—none of which has been truly effective. However, as we have learned more about the anatomy and physiology of the hair, it has become clear that optimal graft survival and ultimate hair growth depend on transplanting more than just the bare hair shafts.

Slightly chubby grafts and intact follicular unit grafts thrive much better, as demonstrated by Seager in 1997. Dissecting a micrograft to the bare hair shaft deprives it of vital structures that ensure its survival. Whether it is the perifollicular vascular plexus, the sebaceous glands, or other appendages that are necessary for survival is unknown. Seager reported 113% hair survival and growth with follicular unit grafts. Presumably, hairs that were in the telogen phase were not initially counted but ultimately grew hair. These hairs in the telogen phase are also included when slightly chubby micrografts and minigrafts are transplanted.

Concluding Thoughts

It is extremely important that all surgical assistants have a clear understanding of the anatomy of the hair follicles. The ultimate result of hair transplantation will depend to a great extent on the accuracy of their dissection of the donor strip into grafts. Minimizing transactions of hair follicles and hair shafts is very important, and they must be handled atraumatically.

Clinical Caveats

When harvesting the donor ellipse, the surgeon must keep the incision superficial to the fascia to preserve the occipital nerves and vessels. Dissection should separate the plane between the subcutaneous tissue and fascia.

The elasticity of the scalp in the donor area is usually greatest in the midline and becomes less elastic laterally toward the ears and temple.

The density of hair is usually greatest at the midline and diminishes as one proceeds laterally.

Continued

Clinical Caveats—cont'd

Minigrafts and micrografts should be inserted in the recipient site following the same angulation and orientation of the residual hair to mimic the natural direction of hair growth.

The epidermis of the graft should remain superficial to the epidermis of the scalp to avoid ingrown hairs and epidermal inclusion cysts.

Minimal incisions at the recipient site will avoid detectable scarring.

Grafts larger than one follicular unit will produce an unnatural appearance because of compression.

CHAPTER 19

Clinical Decision-Making in Hair Transplantation

ALFONSO BARRERA

To date, we have no method for creating new hair where none exists. All current techniques for hair restoration involve redistributing the patient's existing hair. Therefore candidates for hair transplantation are limited to those who have a favorable donor site surface area and hair density relative to the size of the area to be transplanted. Several centers worldwide are working on tissue engineering in an attempt to clone hair follicles or culture and multiply hair follicles in the laboratory setting. When this is successful, we will be able to treat patients with limited donor hair and will need only harvest a sample of hair follicles.

Unfortunately, male pattern baldness is a progressive condition. However, the rate of hair loss may slow down after an individual is about 40 years of age, although it never stops completely. Thus the preoperative plan must ensure a natural-looking, long-term result.

Preoperative Assessment

Careful patient selection and good communication are essential. Patients must have realistic expectations about the result that can be achieved. They must understand that the procedure involves redistributing their existing hair and that currently there is no method for creating new hair. Therefore there are limits to the hair density that can be expected. To obtain the best result possible often takes two sessions and in some cases three; however, a reasonable improvement can often be obtained in just one megasession.

I have found that patients under 30 years of age are often the most demanding. They must understand that because they are young, it is impossible to determine in advance the endpoint of their hair loss. A conservative approach is recommended in these cases.

When patients receive proper instruction and have realistic expectations, I have found that 97% are satisfied after a single hair transplantation session. The 3% of patients who have been dissatisfied with their hair density after surgery have subsequently undergone second sessions to improve the density and were ultimately pleased with the results.

Hair-Loss Patterns

The most frequent types of hair loss include male pattern baldness, postsurgical alopecia, posttraumatic alopecia, and congenital hair loss.

Male pattern baldness is by far the most frequent type of hair loss, followed by androgenic (pattern) alopecia in females.

Postsurgical alopecia (*left*) may occur after oncologic resection of the scalp or eyebrows. After facial rejuvenation or craniofacial procedures, loss of sideburns and of frontal, temporal, and/or retroauricular hair is not uncommon. Posttraumatic alopecia (*right*) includes hair loss from injuries such as burns, traumatic injuries of the scalp and eyebrows, and scalp avulsion.

Examples of congenital hair loss include the absence of mustache hair in cases of bilateral cleft lip (not obvious until after puberty), triangular temporal alopecia, and nevus sebaceous of Jadassohn.

Classification

NORWOOD CLASSIFICATION—MALES

The most commonly used classification system for male pattern baldness is the one described by Norwood:

- | | |
|----------------------------|---|
| Type I | There is minimal or no anterior hairline recession at the frontotemporal areas. |
| Type II | Triangular, symmetrical frontotemporal recessions extend posteriorly no more than 2 cm anterior to a coronal plane drawn between the external auditory canals. |
| Type III | The frontotemporal recessions extend posteriorly beyond 2 cm anterior to a coronal line drawn between the external auditory canals. |
| Type III _{vertex} | Hair loss is primarily in the vertex area but may be accompanied by a frontotemporal recession that does not exceed that described for type III. |
| Type IV | The frontotemporal recession is more severe than in type III. Hair is absent or sparse hair in the vertex area, but both areas are separated by a band of moderately dense hair that goes across the top of the head. |
| Type V | Hair loss in both the frontotemporal and vertex areas is more extensive and is only separated by a narrower and sparser band of hair across the top. |
| Type VI | The band of hair that separated the frontotemporal area and vertex is gone. The two areas are interconnected. The entire area has extended laterally and posteriorly. |
| Type VII | This is the most severe form of male pattern baldness. There is only a narrow horseshoe-shaped band of sparse, fine hair. |

NORWOOD CLASSIFICATION—MALES

Norwood also described a less common variant (type a) that applies to about 3% of cases of male pattern baldness; in this variant the baldness starts at the anterior hairline without a peninsula of hair and advances in a posterior direction. The type a anterior variance patterns are classified as follows:

- Type IIa The entire anterior hairline is high on the forehead. The midfrontal peninsula is represented only by a few sparse hairs. The area of denudation extends no farther than 2 cm from the midfrontal line.
- Type IIIa The area of denudation essentially reaches the midcoronal line.
- Type IVa The area of alopecia extends posterior to the midcoronal line.
- Type Va This is the most advanced degree of alopecia and extends farther posteriorly. If it progresses, it may be indistinguishable from types V and VI.

LUDWIG CLASSIFICATION—FEMALES

The most common classification system used for female androgenic alopecia is the Ludwig classification, grades I through III. Thinning is usually more generalized, in most cases sparing the front hairline, with significant thinning of the vertex, temple, and parietal areas. The occiput tends to be the only area of reasonably good hair quality and density. Women who develop androgenic alopecia do not necessarily have an abnormal increase in circulating androgens or hormonal imbalances; many, in fact, have normal adult female androgen levels. It may be that the androgen receptors in the hair follicles are hypersensitive to or have a greater binding affinity to dihydrotestosterone, which may or may not be genetic in origin.

Indications and Contraindications

Based on the principles we have learned for the treatment of male pattern baldness, and with slight modifications, we are able to help most cases of hair loss by transferring primarily micrografts (one- and two-hair follicular unit grafts) and minigrafts (three- and four-hair follicular unit grafts). In select cases, flaps or tissue expansion may be used. The following patient examples represent the range of clinical challenges encountered in a hair restoration practice.

Patient Profiles

This 32-year-old man with male pattern baldness type IV had good donor hair; his hair is coarse, which can help to obtain nice coverage in one session. He underwent 1500 follicular unit grafts in a single session, primarily to the frontal scalp and a few to the crown.

Further grafting to the crown should be deferred until the patient is older, when his hair loss pattern can be more accurately assessed and the amount of donor hair available determined. The patient must understand that because of his young age, further sessions will be needed in the future as hair loss progresses.

This 53-year-old man with male pattern baldness type VI is an ideal candidate, because his pattern of hair loss is well established and will probably not change dramatically. In such cases a maximal density procedure (2000 to 2500 follicular unit micrografts and minigrafts) can be planned. His donor hair has good density and thickness, and the entire area of baldness will be grafted. A hairline pattern consistent with the patient's mature age is the preferred approach to produce the most natural result. Thus a slight frontotemporal recession will remain.

This 56-year-old man with male pattern baldness type VI had a more mature pattern of baldness than the previous patient. Although his hair loss will continue to progress, his hair-loss pattern as he ages can be better determined, making a more aggressive approach acceptable. He had a reasonably good, dense donor area and a well-established pattern of baldness. He underwent 2040 follicular unit grafts in one session (megasession).

This 43-year-old man has male pattern baldness type III_{vertex} without frontotemporal recession. The density and thickness of his donor hair are excellent. The front part of his scalp is covered with healthy, full hair. His pattern of baldness is well established and limited to the crown. I recommended two sessions of micrografts and minigrafts a year apart to achieve an optimal result. The crown typically will take at least two sessions to obtain reasonable coverage. Although the whirl can be reconstructed by orienting the grafts in a circular orientation, it probably does not warrant the additional time and effort.

This 42-year-old man presented with male pattern baldness type VII, the most severe form of male pattern baldness. There was insufficient donor hair to transplant the entire area. Flaps, tissue expansion, and scalp reduction were treatment options because of the sparse donor hair and extensive area of baldness. I advised a session of 1300 follicular unit micrografts and minigrafts only to the median forelock area, the rhomboid-shaped area on the front part of the scalp. Even though his crown will remain bare, strategic transplantation to this area will help frame his face. He is shown 1 year postoperatively. The hair on the top of his head blends naturally with the temporal fringes.

This 37-year-old man has male pattern baldness type IV. His coarse, wavy donor hair will provide good coverage. Because his hair loss is not very severe, approximately 700 to 800 follicular unit micrografts and minigrafts should be sufficient to strengthen both the front scalp and crown. He must be forewarned that there will be further temporary thinning. The hair must be continuously parted as the grafts are inserted; however, it is not necessary to shave the residual hair in the recipient areas.

This 43-year-old woman had Ludwig grade II to III female androgenic alopecia. Patients such as this tend to exhibit uniform thinning over the entire scalp with preservation of the front hairline. Candidates for the procedure must have an area with good hair quality and density, which tends to be in the occipital region. I recommended that this patient undergo a megasession of 1000 follicular unit micrografts and minigrafts. The patient was forewarned that she could expect further temporary hair thinning for the first 3 to 4 months in the area grafted (telogen effluvium). I recommend that female patients use 2% minoxidil twice a day postoperatively to help preserve and thicken the existing hair as well as the grafted hair.

This 50-year-old woman was concerned about her hair thinning on the front of her scalp. Because she had good density on her remaining scalp, I recommended a session of 400 micrografts and minigrafts. This treatment added hair precisely where needed and was easily performed with the patient under local anesthesia with mild intravenous sedation. I would not advise scalp flaps, strip grafts, or tissue expansion in such a case. These treatments would have been excessive, causing a scar at the front hairline, and she would have had to endure an unpleasant expansion phase. Her postoperative results are very natural, without any detectable scarring.

Preoperative Planning

Aesthetic Considerations

An average scalp is approximately 500 cm² (50,000 mm²). The normal nonbalding scalp has one follicular unit/mm², and each unit contains an average of two hairs (that is, a density of 2 hairs/mm²), so there are approximately 100,000 hairs on the head. Of course, this varies from patient to patient.

The appearance of fullness has to do with hair mass, which is related to the number of hairs, the thickness of the individual hair shafts, texture and color, and curliness. Furthermore, the contrast of colors between the scalp and the hair has a significant influence on the optical illusion of fullness. Most experts today agree that the average healthy, nonbalding patient has a density of about 200 hairs/cm² (range 130 to 280 hairs/cm²) and that only 100 hairs/cm² (range 65 to 140 hairs/cm²) are needed to give an appearance of normal density.

19-1 Hair
transplantation with
micrografts and
minigrafts

Realistically, this number of micrografts and minigrafts can be transplanted in two sessions. To obtain a surgical result that mimics nature, a large number of randomly transplanted small grafts (follicular unit-sized grafts) is essential, providing a result unmatched by any other method of hair restoration. Patients should be advised that two sessions and occasionally three sessions may be necessary to obtain the desired density. Often, however, significant improvement is seen after just one session, and results will persist for years without a repeat procedure.

If the ratio of donor site to recipient area is favorable, I transplant the entire area of baldness. If the ratio of donor site to recipient area is not favorable, I may only transplant the front hairline or a median forelock. If it is clear that there is insufficient donor hair, it is better not to proceed with transplantation. It is a judgment call.

When feasible, I prefer to transplant the entire bald area, with a focus on providing the greatest density possible at the front hairline. Patients can style their hair so that it layers farther back to give the visual appearance of density in the back.

Design of the Hairline

The design of the hairline or the area to be transplanted is crucial, the idea being to mimic nature as much as possible. The position of the front hairline is critical for a natural result; conservatism is in order. The goal is to achieve a mature hairline. The size and shape of the head vary among individuals, as does the position of a mature hairline. Generally, the midline of the new hairline is approximately 8 cm from a horizontal line immediately above the eyebrows. In some patients a slightly longer or shorter distance is appropriate, depending on the facial features, shape, and size of the head as well as the interrelationship and proportions of the face and skull.

Donor Site Harvesting

The many variables encountered during donor site harvesting test the surgeon's clinical judgment. The size of the donor ellipse varies, depending on the number of grafts planned or the size of the area to be grafted, as well as the density of the donor site and the pliability and elasticity of the donor scalp. Only the amount of scalp needed should be harvested, yet the surgeon must ensure that enough donor scalp is obtained for the number of grafts planned and that the donor defect can be closed under minimal tension.

The laxity of the scalp varies from person to person. The surgeon must be alert to the presence of scar tissue from previous procedures since this will result in reduced elasticity and pliability of the donor scalp. Most patients' scalps permit ellipses 1 to 1.5 cm wide to be harvested with minimal tension on closure. The surgeon must feel the donor scalp to assess the laxity, elasticity, and pliability.

A long, narrow, horizontal donor ellipse is preferable to a short, wide ellipse. Hair density as well as the elasticity of the donor occipital site is usually greater toward the midline. The hair becomes sparser and the scalp less elastic more laterally. The scalp above the ears is usually quite inelastic. These factors must be taken into consideration so that the ellipse can be designed to allow closure with minimal tension.

Normally the hair density in the donor area is approximately 200 hairs/cm² (range 130 to 280 hairs/cm²). The diameter of the individual hair shafts varies from 0.06 to 0.14 mm.

Assuming a density of 150 hairs/cm², an ellipse 10 by 1 cm will yield approximately 1500 hairs. Naturally occurring follicular units have 1 to 4 hairs per unit. These units must be kept intact as much as possible. The exact number of grafts can only be determined after dissecting the donor ellipse into grafts, but an ellipse of this size will yield approximately 500 to 600 grafts.

If hair density is approximately 150 hairs/cm², a horizontal, occipital donor ellipse of 20 by 1 cm with 3375 hairs will be needed to produce 1000 to 1200 micrografts and minigrafts (1 to 4 hairs per unit).

A maximal density procedure (2000 to 2500 grafts) in patients with types VI or VII male pattern baldness makes harvesting enough donor tissue a greater challenge. In these cases I harvest a horizontal ellipse approximately 30 to 32 cm long and 1 to 1.5 cm wide at the midline (scalp elasticity permitting), gradually tapering the width laterally to 1 to 0.5 cm at the ends. In most patients this yields approximately 2000 to 2500 follicular unit micrografts and minigrafts and between 5000 and 6000 hairs.

Donor Site Dimension Guidelines

Micrograft and Minigraft Follicular Units (number of hairs)	Hair Density (hairs/cm ²)		
	150 (low)	200 (average)	201-250 (high)
500-600 (±1500 hairs)	10 × 1 cm ellipse	6-7 × 1 cm ellipse	5 × 1 cm ellipse
1000-1200 (±3000 hairs)	20 × 1 cm ellipse	15 × 1 cm ellipse	10 × 1 cm ellipse
1500-1800 (±4500 hairs)	25 × 1 cm ellipse	20 × 1 cm ellipse	15 × 1 cm ellipse
2000-2500 (±6000 hairs)	30 × 1.5 cm ellipse	30 × 1 cm ellipse	25 × 1 cm ellipse

NOTE: All ellipses 1.0-1.5 cm in width, tapering only at the 1.0-0.5 cm ends.

Camouflaging Scalp Scars

Patients are often seen with scars on the scalp or the front hairline as a result of accidents, surgical interventions, and poor healing after an aesthetic surgical procedure. Micrografts and minigrafts alone can frequently benefit such patients.

Even when incisions are made parallel to the hair shafts on the scalp or on the hair-bearing skin (eyebrows, beard, or mustache) and closed without significant tension, a fine hairline scar is often inevitable. These scars are sometimes detectable because of the absence of hair at the scar line. Micrografting and minigrafting offer an excellent solution for these deformities. The technique is basically the same as that described earlier except that the direction of the graft insertion may be more critical for controlling the direction of hair growth.

When working on the temporal hairline, eyebrows, or mustache, for example, the direction of the natural hair growth at the respective sites must be followed. Micrografts and/or minigrafts can be added at the newly closed wound suture line in hair-bearing incisions. These small grafts thrive well even if the blood supply is precarious and will help minimize hair loss at the incision site. The use of atraumatically dissected micrografts and minigrafts and closure under minimal or no tension are key to the success of this approach.

When feasible, it is best to make the micrografts and minigrafts from hair-bearing areas surrounding the wound (local hair), especially for the eyebrows (the contralateral eyebrow or residual hair from the same eyebrow), because they normally exhibit a very different growth pattern than that seen in scalp hair.

This 15-year-old girl had an otoplastic procedure performed. A tight dressing placed around the head and knotted at the front hairline level resulted in a pressure sore and loss of hair in an area about the size of a half dollar.

The area of alopecia was excised, but an area of hair loss remained. Scar revision by a plastic surgeon left a widened scar. The patient was referred to me for further revision and/or micrografting. I reexcised the scar and placed micrografts along the suture line closure and a few micrografts at the scar's perimeter. About 25 micrografts and minigrafts were placed at the closure line and 25 around the closure.

Correction of Sideburns After Face-Lift Procedures

Surgeons who perform face-lift procedures acknowledge that upward displacement of the sideburn, temporal hairline, and retroauricular hairline is not uncommon, especially in patients undergoing secondary face lifts. The sideburn is an important aesthetic unit of the face.

Sideburn loss is a telltale deformity unique to face-lift procedures. Patients attempt to style their hair to camouflage the area, but this may be futile if they live active outdoor lives. Such upward displacement can often be prevented if prehairline incisions are used. If sideburn loss does occur, it can be corrected with various scalp flaps, but I prefer the use of micrografts and minigrafts for several reasons:

1. A natural result can be achieved in just one session.
2. The direction of the hair can be controlled by angling the surgical blade.
3. The desired hairline design can be followed with precision.
4. A transition zone can be readily created that avoids a scar in front, a common sequela of flap techniques.

This 52-year-old woman came for a consultation 3 years after a face lift. In a single session, 850 follicular unit micrografts and minigrafts per side were transplanted to restore the lost sideburns, temporal hairline, and some at the front hairline. Postoperatively, blending of the grafts with the natural direction of hair growth is evident.

Restoration of the Eyebrows, Mustache, and Beard

Fujita first described the use of single hair grafts to reconstruct the eyebrows in 1953. This was the first mention of the use of micrografts since Tamura reported transplanting single hair grafts from the pubic area in 1943. It would be another four decades before there was further experimentation with small grafts. More recently, Gandelman published his superb results using micrografts and minigrafts to restore the eyebrows.

Fortunately, micrografts and minigrafts grow anywhere on the face and thus are useful for restoring the eyebrows, mustache, and beard. However, because the consistency of facial skin is softer and more elastic than that of the scalp, the surgeon will encounter more problems with grafts popping out when transplanting facial areas.

This 54-year-old man desired thicker eyebrows and more density in his frontotemporal region.

He underwent scar revision for a previous direct approach brow lift (done elsewhere) plus a slight brow lift. I advised a session of 250 grafts to the frontotemporal recession areas and about 150 grafts to each eyebrow. Because of his thin eyebrows, donor hair was taken from the lateral occipital area. He is shown 1 year postoperatively. The density and natural direction of the hair and absence of scars are evident.

This case presented the challenge of choosing the optimal donor site for eyebrow hair. If a patient has unilateral eyebrows with high contralateral density, donor hair can be taken from the existing eyebrow. However, when the patient has thin eyebrows bilaterally, other options such as axillary, pubic, and scalp hair must be explored. The caliber of individual axillary or pubic hair is generally too thick, and both have textures different from eyebrow hair. Although it seems ideal to obtain donor hair from the nape of the neck, the caudalmost part of the occipital area,

I prefer not to harvest from this region because of the increased risk of hypertrophic scarring. In addition, as we age, hair recedes from a caudal to a cephalic direction. Therefore I look primarily at the lateral occipital area, not the retroauricular, as the ideal potential donor site.

Treatment of Burn Alopecia

Various methods have been used for the treatment of burn alopecia, including punch grafts, local scalp flaps, free scalp flaps, and tissue expansion. The fibrotic scar tissue that normally forms after burn injuries has a precarious blood supply and is not an optimal site for any type of graft. Single- and double-hair grafts (micrografts) and grafts with three to four hairs (small minigrafts) have fewer metabolic requirements because of their small size, which probably permits them to survive in this hostile environment.

Having seen these small grafts survive in patients with male pattern baldness who had scarred scalps from previous surgical procedures, I decided to try them in patients with burn alopecia. The success of this approach has been reported in the literature.

I think that it is important to allow sufficient time for the scalp to heal, soften, and fully recover from the insult of surgery or trauma before proceeding with hair transplantation, especially in the case of burn alopecia.

This 18-year-old woman developed chemical-burn alopecia after applying highlights to her hair. She had very high density in the surrounding areas and requested quick results, because she was leaving for college in a few months. Follicular unit micrografts and minigrafts would have provided a nice result but would have taken at least two sessions and perhaps three to blend reasonably well with the surrounding hair density. Furthermore, the sessions would have to be performed at least 6 to

8 months apart and would take 1½ to 2 years to complete. Scalp reduction was not an option, because her scalp was a bit tight. Even though serial excisions might have improved the tightness, it would have been repetitive and would have resulted in a hairless scar line at best. Therefore I recommended tissue expansion with micrografts inserted between the sutures during closure.

Tissue expansion was performed using a 350 cc crescent-shaped expander inflated to 210 cc. The expander was removed after 3 months.

With the patient under conscious sedation and local anesthesia, the areas of alopecia were excised by tailoring the expanded scalp. The wound was closed with a simple running 3-0 Prolene suture. Approximately 50 grafts were placed between sutures to further camouflage the closure. She is shown 3 months postoperatively with excellent hair density.

This 43-year-old man sustained severe third-degree burns to his upper body, chest, neck, face, and scalp. He underwent multiple surgical procedures, including rib-graft ear reconstruction. He was referred to me for restoration of frontotemporal, left frontotemporal-parietal, sideburn, and eyebrow hair. He requested postponing eyelash reconstruction. I recommended a single session of 1525 follicular unit micrografts and minigrafts to both temples and the frontal hairline and 125 grafts to each eyebrow. He is shown 8 months postoperatively. He returned for a second session to further increase his hair density.

Eyelash Reconstruction and Augmentation

The eyelash of the upper eyelid is an important structure both functionally and aesthetically. The upper eyelashes resemble a cantilever, preventing the entrance of small foreign bodies that may cause microtrauma to the conjunctiva and cornea. Eyelashes contribute to the aesthetic appearance of the eyes and face. Lack of eyelashes can result in a strange, owl-eyed appearance that is both embarrassing and damaging to the self-esteem. Eyelash reconstruction is suggested for the following conditions:

1. Congenital absence of eyelashes
2. Eyelash loss from traumatic injury, burns, or dermatologic disease
3. Eyelash loss caused by oncologic surgery or radiotherapy
4. Iatrogenic loss resulting from the use of silver nitrate to prevent trachoma

Some anatomic features are especially noteworthy for successful eyelash reconstruction. The central portion of the orbicularis oculi muscle covering the eyelid is referred to as the palpebral portion. This is further divided into the *preseptal* and *pretarsal* muscles based on their relationship to the underlying orbital septum and the tarsal plate, respectively.

This illustration of a sagittal section through the upper eyelid shows the superficial and middle structures of the upper eyelid, including the levator aponeurosis, preseptal and pretarsal portions of the orbicularis oculi muscle, and the eyelid skin. The drawing also demonstrates the relationship of the pretarsal portion of the orbicularis oculi muscle, eyelash hair follicle, and eyelid skin.

The pretarsal muscle is firmly attached to the underlying tarsal plate. However, the upper part of the upper pretarsal muscle is attached to the levator aponeurosis and thus is separated from the tarsus at that point. There are approximately 100 to 150 lashes on the upper eyelid. The eyelashes emerge in two to three irregular rows from the eyelid margin anterior to the *gray line* (mucocutaneous junction). Sweat glands (Moll) and sebaceous glands (Zeis) enter the follicular structure of the cilia. The skin of the eyelids is the thinnest of the entire body. There is a thin fascial layer between the skin and the orbicularis oculi muscle. There is virtually no subcutaneous fat in this area, and the skin is tightly applied over the pretarsal muscle and loosely adherent to the preseptal muscle.

This 23-year-old man requested restoration of a small segment of eyelashes in his left lower eyelid. I recommended one strip graft and a total of five micrografts to both the upper and lower eyelids. He had dense eyebrows, and since the area of demand is small, I elected to harvest a small donor strip from the contralateral eyebrow. I selected a spot that had good density with desirable hair direction. The strip was turned and positioned in the most desirable orientation to mimic the missing eyelashes as best as possible. He is shown immediately after surgery with the scleral shield still in place and 1 year postoperatively.

I decided to choose eyebrow hair for the donor strip, because its features are similar to those of eyelashes. Although it is a challenge to encourage transplanted eyebrow hair to grow in the same direction as natural eyelashes, a strip graft, rather than follicular unit grafts, provides additional control.

Choosing the Best Option

	Scalp		Strip Grafts	Eyebrow Donor	Tissue Expansion
	1-2 Hair Follicular Unit Micrografts	3-4 Hair Follicular Unit Micrografts			
Male pattern baldness					
Female pattern baldness					
Lost sideburn and retro-auricular area hair					
Scalp burn alopecia and scalp-scarring alopecia					*
Eyebrow restoration*			*		
Eyelash restoration			*	*	
Moustache and beard restoration					
Pubic hair restoration					
Body and lower leg					

*In selected cases.

Clinical Caveats

The follicular units should be maintained as intact as feasible.

For patients with dark hair, 3.5 loupe magnification and background lighting are sufficient to dissect most grafts as follicular units.

For patients with light hair or gray hair, surgical microscopes and background lighting may be needed for more accurate dissection.

Always consider which donor area is most desirable. In most cases, it is the occipital area; for eyelashes and eyebrows I usually use scalp hair, but pubic hair may be considered for eyebrow reconstruction.

CHAPTER 20

Micrograft and Minigraft Megasections in Hair Transplantation: *Current Techniques and Future Directions*

CARLOS OSCAR UEBEL

Hair loss, whether partial or complete, is the cause of significant concern to both men and women, who view it as unaesthetic and a visible sign of aging. Consequently, as our population ages and techniques for hair transplantation improve, the demand for hair restoration has grown significantly. Today surgical replacement of the hair has become an increasingly common and popular procedure in the field of male plastic surgery; it has been embraced by politicians, movie stars, and businessmen alike as they seek to reverse the progressive hair loss associated with the aging process. Women are also requesting this procedure to address alopecia and to correct deformities secondary to face-lift procedures. In the first part of this chapter I describe the basic techniques currently performed; the second part focuses on new developments and the potential role for platelet-rich plasma growth factors.

Evolution of Technique

The beginnings of modern hair transplantation procedures can be traced back as early as 1943, when Tamura of Japan successfully transplanted pubic hair; this was followed by Fujita in 1953, who transplanted hair for eyebrow reconstruction. However, it was not until 1959 that hair transplantation became popular when Orentreich introduced the use of punch grafts. He also introduced the concept of *donor dominance*, which is central to hair transplantation. This concept asserted that individual hair follicles had their own hereditary characteristics that are preserved after transplantation, enabling the hair to grow at the recipient site with its inherent characteristics preserved. Although the punch procedure provided a mechanism for hair transplantation to address male pattern baldness, the results were often unnatural and obvious.

In an effort to improve the aesthetic appearance of transplanted hair, temporoparietooccipital (TPO) flaps were introduced by Juri, with subsequent improvements by Chajchir et al and Uebel. Although scalp pedicle flaps from the parietal and occipital areas produced acceptable aesthetic results in patients with male pattern baldness, there were two distinct disadvantages. Even though it was well integrated, the flap was visible as a camouflaging patch, and the residual scar at the border of the hairline was conspicuous. It was not until the 1980s, with the introduction of the micrograft concept by Nordström and Marrit, that these problems were solved and surgeons were able to create a more natural-appearing hairline. This served as the basis for further advances and refinements, culminating in the introduction of micrograft and minigraft megasessions in 1986. I published reports on this technique in 1989 and 1991, which I called the *micropunctiform technique*; I have been perfecting this procedure since its introduction. Today this technique has become widely ac-

cepted by surgeons and patients as a simple and safe procedure that recreates predictably natural and aesthetic hairlines for most patients with various degrees of hair loss. The unnatural clumps, rows, strips, or flaps so typical of early procedures have now been replaced with random-pattern hairlines with feathered, natural borders. We have truly entered a new age of hair transplantation that offers the surgeon a valuable tool for addressing male and female pattern baldness, as well as other hair loss problems associated with disease or aesthetic surgery.

Indications and Contraindications

Although male pattern baldness is often associated with the aging process, it can also occur in younger patients, beginning as early as 16 years of age. It results from three main factors: heredity, androgenic hormones, and age. It is progressive in nature, and its growth cycle becomes more evident after age 30. In women, hair loss seems to occur more frequently during menopause, but androgenic female alopecia can occur at an earlier age.

Hair restoration procedures are appropriate for men and women of all ages and in patients with partial or moderate balding. Careful patient selection and good communication are crucial. Patients must have realistic expectations of what can be achieved. Because there is no means of creating new hair, they must understand that hair transplantation is ultimately a method for redistributing their available hair, and the success of the procedure depends on the condition of the donor area as well as on the density and quality of the hair to be transplanted.

The micrograft/minigraft technique is very effective in older patients in helping them to achieve a younger look. The new hairline reframes the patient's face with a natural, elegant profile. In women, this technique is indicated for androgenic baldness; it is also very effective in patients undergoing secondary face and forehead lifts for reconstructing sideburns and improving the temporal recesses.

I prefer to operate on patients who are at least 24 years old, because by that age they are more aware of the progressive nature of their hair loss, are truly certain of what they want, and are usually mature enough to understand that they may need to undergo one or more additional procedures in the future. Patients should always be honestly informed of the necessity for any reoperative procedures to maintain hair density. Surgery is not recommended for patients with diabetes or coagulation disorders as evidenced by a prothrombin level of less than 75%.

Preoperative Assessment

History and Testing

As is standard with all operative procedures, a complete history is obtained, including previous illnesses and surgeries. After the patient has been assessed and a surgical plan defined, the following laboratory tests are performed:

- Complete blood cell count
- Glucose test
- Coagulation test
- Electrocardiogram for patients over 50 years of age

We do not require any complementary examinations, because hair transplantation procedures are performed on an outpatient basis with the use of local anesthetic and sedation.

Evaluation of Hair Characteristics

Hair can be divided into different categories to help the surgeon assess each patient's requirements and develop a realistic plan for hair restoration. Griffin established the following four important characteristics for evaluating the hair in patients undergoing hair transplantation:

1. Color: black, brown, red, blond, or gray
2. Texture: coarse, medium, or fine
3. Skin-to-scalp contrast:
 - High contrast: black hair on fair skin
 - Low contrast: red hair on ruddy skin
 - Medium contrast: brown hair on olive skin
4. Degree of curl: kinky, curly, or straight

Norwood added two more factors for proper patient assessment:

5. Density
6. Size of donor area

To these classifications, I have added two other hair types that are very common in patients of European descent and in the patients I see from southern Brazil:

7. White hair
8. Wavy hair

Hair Density

Hair density is an important factor in hair restoration. As can be seen in these three individuals, density varies from one patient to another; the younger the patient, the denser the hair. One of the best techniques for improving hair density is to place additional grafts in between the remaining hair. Patients are satisfied with the results and are able to change hairstyles and color. In the third patient, the natural aging progression of follicular units is demonstrated. He is seen preoperatively at age 42, 3 years after transplantation at age 45, and 13 years after the procedure at age 57.

Hair Thickness

Hair thickness must also be considered. Coarse hair usually covers baldness more effectively than fine hair does; however, the shafts of thick hair tend to be more visible and detectable. With fine shafts we can achieve a better hairline, although it is less dense, often making repeat procedures necessary. Wavy and kinky hair works well in hair restoration and provides better coverage of the bald area.

Hair Color

Special care is needed when transplanting black hair, especially if it is coarse and implanted on a bright, oily surface. In these cases the contrast is high, which results in an artificial appearance. A random distribution of implants is recommended, and the temple recessions should be maintained to create a natural appearance. Patients who have thick, dark hair are encouraged to modify their hairstyles by combing the hair to the front or to the side.

Brown hair is usually found on young patients with incipient baldness. It is easier to work with than black hair. Its contrast against the scalp is lower, and the result is aesthetically more natural. This type of hair will gray with age, improving the surgical result.

Gray hair is typically found on patients over 60 years of age. In older patients the hair becomes fine, and its contrast with the scalp is minimal. Hair transplanted from the neck is usually darker, and this mixture of gray and dark hair produces a more youthful appearance.

Red hair is rare; it maintains its color or lightens with age, giving patients a youthful appearance. In most cases, red hair is accompanied by ruddy skin and scalp. These patients are often freckled.

Blond hair offers the best results in hair restoration. It is usually fine, and its contrast to the scalp is minimal. In most cases, to achieve good density, two or three transplant procedures must be performed.

The root of white hair is very difficult to work on, because the absence of melanin in the hair bulb and shaft make the root almost imperceptible when the follicular units are being prepared. However, the aesthetic result is very pleasing.

Texture

Coarse hair is very good for transplantation. The preparation of follicular units is easy, and the desired density often can be achieved in the first procedure. A natural hairline is often difficult to obtain. Therefore the texture of the donor area needs to be assessed, and the patient must be aware of this tendency. Care should be taken to implant the hairs *one at a time* and in an irregular dispersal pattern to achieve a natural result.

Fine hair is sometimes found on young patients but is more frequently found on individuals 40 years of age and older. The aesthetic result is better than with coarse hair, although the hair density is lower. A second replacement procedure after 1 year is essential.

Skin-to-Scalp Contrast

Black hair on fair skin has a high contrast. This is usually seen in patients with oily skin. The surgeon should be honest and explain that even after two or three replacements are performed, the results will be detectable. Patients in this category are instructed to wash their hair with a shampoo for oily hair to keep the hair as oil free as possible. Some patients use skin blush to diminish the high contrast.

Degree of Curl

Kinky and curly hair is typically found on individuals of African descent, Arabs, and people of Middle Eastern origin. It is more difficult to separate the follicular units because of their curly form; however, this hair type covers and protects the scalp better than other kinds of hair. The density and aesthetic result are superior to what is achieved with other hair types.

Wavy hair provides the patient with different hairstyle options and good natural density.

The aesthetic result from straight hair is good, but maintaining a hairstyle often proves difficult. Usually two replacement procedures are required to achieve natural density. We recommend that patients use gel to hold the hairstyle in place.

Photographic Documentation

Pictures are very important at all stages of hair restoration surgery. We take color photographs (ISO 100/21 degrees) and digital photographs with a 5.0-megapixel camera. Preoperative images are taken with the patient sitting and the head positioned at a 45-degree angle. The front and right and left sides are photographed, and when the crown area is included, a picture is taken from behind. These images help the surgeon evaluate the new hairline, assess the area of baldness, and estimate the quantity of hair to be replaced.

Postoperative pictures are usually taken 8 months after the transplantation procedure for men and 12 to 15 months after transplantation for women. It is important to allow enough time to pass so that the final result can be adequately estimated. Postoperative photographs must be of the same quality as those taken preoperatively. It is very important for the photographer to maintain the same distance from the patient and to duplicate the views and angles of the preoperative images so the post-procedure images are comparable. When in doubt, the preoperative photos should be reviewed.

The proper preoperative and postoperative views and positions are demonstrated. A close-up view of the hairline using a macro lens is helpful to detail the new hairline (see p. 648). A complementary photograph taken from behind showing the horizontal scar and donor area can be included if necessary for planning a second replacement procedure.

Patient Education

Each step of the procedure is explained to the patient. Surgeons should always be honest when discussing the positive and negative aspects of hair replacement. Baldness is progressive in nature, and the transplanted hair will undergo the same aging process as the hair of the donor area, becoming finer and changing color. It is especially important to make the patient aware that a second procedure may be necessary to maintain the new hairline. Honesty will increase the patient's confidence, and he or she will become an ally and collaborator in establishing the surgical plan.

Pertinent Anatomy

The growth cycle of hair is divided into three distinct phases: anagen, catagen, and telogen. Anagen, the adult phase, lasts approximately 6 years. In this phase, hair grows exuberantly and naturally. Catagen, the involution and loss of hair, lasts 2 to 3 weeks. In this stage, hair is lost on pillows, on combs, and in the shower. Average hair loss during this phase is approximately 100 hairs per day. After the involution of the follicle, the telogen phase begins and lasts from 3 to 6 months. This is the preparation phase for new hair. During this phase, fine hair begins to grow and lasts for 6 years. Implanted hair, with its preserved genetic characteristics, maintains this cycle.

An anatomic/histologic structure of the scalp was described by Headington. It usually consists of two to four terminal follicles, one to two vellus follicles, sebaceous glands, and insertions of the arrector pili muscles. Surrounding this structure is the perifolliculum, which is formed by reticular dermis collagen fibers.

The key to successful graft survival and ultimate hair growth is knowledge of this anatomy and an understanding that chubby grafts and intact follicular unit grafts have far greater potential for survival than bare hair shafts.

Preoperative Planning

When a new hairline is being designed, the donor area, its density and hair type, and the bald area are evaluated to ensure that there are no dermatologic lesions. The progression of the patient's baldness is also assessed.

Hairline Design

The new hairline is discussed with the patient in front of a mirror, and the new hairline is drawn on the scalp. An irregular frontal hairline will create a more natural and aesthetic result. Temple recessions are maintained to create a more natural appearance. Normally we begin with a perpendicular line from the tail of the eyebrow to the upper scalp, reaching the temple recession area. From this point we mark the frontal hairline.

In young patients it is important to project the definitive frontal hairline. I normally draw a line 2 or 3 cm beyond the original hairline, estimating the future frontal and temporal recesses. In older patients (more than 60 years of age), a more posterior hairline is suggested, sometimes with a design such as a frontal forelock.

Over the years I have established some important parameters for the frontal hairline. The midpoint of the forehead is normally 8 cm from the glabella, varying from 7 to 9 cm, depending on the individual patient's facial contours. I draw a perpendicular line from the brow–lateral canthus up to the temporal recesses. This lateral point will connect with the middle point in a VW irregular line. If necessary, the thin hair and effluvium are raised to make the surgery more effective.

Operative Technique

Donor Area Preparation

The donor area is shaved and the ellipse is marked. The hair follicles are harvested from the posterior cervical area where the hair density is greatest and the quality is best; this is normally 6 to 8 cm from the nape of the neck. I plan to remove a hair-bearing ellipse that correlates to the size of the area of baldness; this area may be small, medium, or large and can vary from 10 by 2 cm to 20 by 3 cm, where 500 to 1500 follicular units can be obtained.

I never count the exact number of hairs to be replaced. Some patients have less density per square centimeter than others, so it is useful to harvest a larger hair-bearing ellipse.

Anesthesia

During the procedure the patient must be kept calm and quiet and in a reclining position. The operation takes approximately 2 to 3 hours, so the patient should be positioned comfortably. Both the surgeon and the patient should be relaxed. A well-trained team is requisite for a good result. Anesthesia is divided into three stages: sedation, nerve blockage, and scalp ballooning.

I normally use midazolam 5 to 10 mg and fentanyl citrate 1 to 2 ml to sedate the patient, and 20 ml levobupivacaine chloride 0.5% with epinephrine 1:200,000 to block the supraorbital nerves and the coronal area 1 cm in front of the hairline.

Scalp ballooning is a procedure that I described in 1991. It is designed to increase the edema of the scalp and to achieve ischemia, which aids in the implantation of the follicular units. The scalp is infiltrated with 160 ml of saline solution containing epinephrine 1:160,000.

All layers of the scalp are infiltrated, from the subgalea to the dermis. This maneuver is important to prevent bleeding during surgery and to maintain the grafts inside the punctiform incision. We wait 5 to 10 minutes before we begin and repeat the infiltration every 30 minutes as necessary.

We also use levobupivacaine 0.5% at the donor site to block the occipital nerve branches and the entire ellipse. The scalp-ballooning technique is also performed at the donor site. The objective of this infiltration is to make the scalp tumescent, thus easing the separation of the follicular units. It also reduces bleeding in this area.

Harvesting the Donor Ellipse

The hair-bearing ellipse is cut with a single No. 10 blade at an oblique angle to avoid damaging the hair follicles. This incision is quite superficial; the flap is raised from the subcutaneous fat layer, with care to avoid dividing the sensitive branches of this region. It is important to avoid causing posterior paresthesia or painful processes such as sensitive neuroma, which may last for months. The galea aponeurotica must remain intact.

In the past we attempted to use multiblades and punches in the donor area, but we found that we damaged many of the hair follicles. This in turn made it more difficult to harvest the area during a second replacement procedure.

To achieve a natural closure, it is very important to undermine the superior and inferior edges of the ellipse, taking care not to damage the occipital vessels and nerves located at the ends of the ellipse. The scalp does not tolerate stretching, so closure must be done gently.

Subcutaneous sutures are placed, and a running superficial cutaneous suture is used to close the defect.

Preparing the Follicular Units

The hair-bearing ellipse is placed on a hard wooden or acrylic surface and cut into several slices, 3 to 4 mm wide, with a No. 22 or No. 10 blade. The movement for cutting the grafts must be fast and precise, maintaining a direction parallel to the shafts and follicles. The subcutaneous fat is removed from the follicles, but care is taken to maintain a small amount around the bulbs. This remaining fat will provide nourishment and protect the bulbs during the grasping maneuver.

Patients with less hair density will present with larger interstices of reticular dermis and connective fibers surrounding the grafts. This tissue is trimmed away during graft preparation so the follicular units may be placed closer together in the recipient area to create density with a significant amount of connective tissue surrounding the grafts that needs to be trimmed away.

In this transverse section of the scalp, at the level of the sebaceous glands in the low reticular dermis, follicles are seen separated by a large fibroconnective tissue (hematoxylin-eosin stain; original magnification 50 $\times$). This tissue is trimmed away, “cleaning” the units for transplantation. Other areas have a density greater than 1 follicular unit/mm².

In this histologic specimen, we see a normal density of follicular units (hematoxylin-eosin stain; original magnification 50 $\times$).

The grafts are divided into two groups: micrografts consisting of one or two bulbs, and minigrafts consisting of three or four bulbs. Both are called *follicular units*.

Grafts can be separated without magnification or with three-dimensional stereoscopic viewing. The use of magnification in the preparation of follicular units has contributed to improved graft quality. Highly skilled and experienced assistants are essential in the preparation of the follicular units. With good lighting and sharp blades, they can accurately prepare 100 to 1000 grafts within an hour.

In preparing the grafts, it is important not to cut the epidermis. We have found that buried grafts produce more cysts and granulomas after the third month, when the hair starts to grow. For the past 12 years we have preferred to maintain the epidermis.

After the grafts are prepared, they are placed on gauze moistened with saline solution and brought to the recipient site immediately; there is no need to place them in solution or wet dishes. To maintain good histologic condition, grafts should be transplanted within 20 minutes of being divided. Through studies described by Limmer, we know that the grafts can be kept out for a period of up to 2 hours without waste. After that, they lose their quality and the yield will be jeopardized. This is an important part of our technique, which allows the grafts to be implanted immediately. As the follicular units are being prepared by two assistants, the surgeon and another assistant are immediately implanting them.

Implantation of the Follicles

The bald recipient area should be swollen and ischemic; it is important to work without bleeding and to maintain the grafts inside the orifices. To achieve this scalp ballooning, I perform tumescent infiltration of all layers of the scalp. As mentioned previously, this can be repeated every 30 minutes, whenever the tumescence and ischemia diminish. It is important to inject the dermal surface immediately before transplantation to achieve a sympathetic and microvascular plexus of the area, which is demonstrated by “white marbling.” The area is then ready to receive the micrografts without bleeding.

To perform the punctiform incision, we use a No. 11 sharp blade, or a microsurgical blade (Beaver 6500-BD). An angular microsurgical forceps is useful to grasp the follicular units and bring them to the slit.

I normally prefer to begin the punctiform incision from the middle and work toward the front. To create a natural hairline, the incision is made vertically in the middle and then a little obliquely as it approaches the forehead. The incision is 3 to 4 mm deep, which is a sufficient depth to gently place the graft. Care must be taken not to cut the galea aponeurotica, because doing so would cause more bleeding and the graft could be totally buried.

When I have made the incision with a No. 11 blade or microsurgical blade, the assistant picks up the graft from the moist towel with an angled microsurgical forceps and gently inserts it into the slit. The blade is then removed to help with insertion. This maneuver, which we call *stick-and-place*, is performed simultaneously.

The stick-and-place procedure is repeated, maintaining a space of 4 to 5 mm between each unit so the implanted grafts are not dislodged. If greater density is desired, I wait 15 to 20 minutes before introducing another graft between the newly implanted units. During this time the fibrinogen inside the skin becomes fibrin and surrounds the grafts like glue, causing them to adhere in place. When the anterior region of the forehead is reached, I implant single hairs in an irregular pattern for an effect that is vital to achieving a natural-looking final result. It usually takes 2 hours to place 1500 follicular units; we do not recommend exceeding this amount. It is preferable to perform a second replacement procedure after 8 months, if necessary, at which time another quantity of grafts can be successfully implanted. *Transplanted units are like plants in that we need to keep a distance of 2 to 3 mm between them so that they will grow with greater vitality.*

When transplantation is complete, a simple dressing of gauze moistened in saline solution is applied over the implanted area, and a bandage is kept in place for 24 hours to protect the area.

Postoperative Care

After the surgery, someone should accompany the patient home. Patients may return to their professional activities the day after surgery. I recommend the use of an analgesic to relieve discomfort in the donor area, which is common 6 to 8 hours after surgery. I do not recommend the routine use of antiinflammatory medication or antibiotics.

During the first 24 to 48 hours, it is important for the patient to sleep with the head elevated at no more than a 30-degree angle to avoid swelling in the forehead, which may occur as a result of the scalp ballooning. Swelling of the forehead occurs in 25% of patients and may, after the second day, move down to the eyelids and even the cheeks. Cool compresses are helpful for reducing the swelling, but steroids do not bring significant improvement.

The tumescent technique produces swelling in the scalp that lasts for approximately 2 days and can affect the face and upper eyelids for up to 3 days. I recommend that the patient not drive during the first 24 hours and sleep in a dorsal or lateral decubitus position at a 30-degree angle for the first 48 hours.

The patient removes the dressing at home on the second postoperative day and showers, gently cleansing the scalp with an antiseptic shampoo. Patients should try to remove only the dry blood but not the crusts, which will slough off within 8 to 15 days. If the patient dislodges any of the implants, there will be some bleeding, which can be stopped by pressing the location for 3 to 5 minutes.

There is a transition phase, catagen, 1 to 3 weeks after surgery, in which the implanted hair grows to 3 or 4 mm. During this stage, the patient can touch the implanted area and feel hair beginning to grow. After this period, the telogen phase begins, during which almost every implanted hair falls out. This phase lasts approximately 6 to 9 weeks, and the patient may worry whether the surgery was a success. After the telogen phase, the anagen phase begins, and new hair will be generated from the remaining matrix. The new hair growth initially comes in very thin and delicate. The final result will be visible after 6 to 8 months in men and 10 to 12 months in women.

Preoperative

3 months

4 months

5 months

6 months

7 months

8 months

This 42-year-old patient shows the progression of hair growth in the first 8 months after hair transplantation.

The same patient is shown preoperatively and 1 year postoperatively.

Patient Instructions Following Hair Transplantation

Plan on relative rest for the first 72 hours. During this period always lie with your head elevated at a 30-degree angle.

After the second day, swelling may occur in the eyelids and the forehead region. If this occurs, apply cold compresses soaked in saline solution or boric acid dissolved in water. The swelling will decrease within 48 hours.

The dressing should be removed on the second postoperative day, and your head must be washed with antiseptic shampoo, taking care to remove only the dried blood, not the crusts. The antiseptic shampoo must be used for a week.

After the dressing has been removed, we recommend covering the implanted area for protection with sterile gauze and a hat or cap.

We advise against any of the following:

- The use of hair dye
- Driving while the eyelids are swollen
- Smoking or drinking alcoholic beverages during the first postoperative week
- Playing sports or exerting yourself during the first 2 postoperative weeks
- Exposure to the sun or intense heat for at least 3 weeks

The stitches in your head must be evaluated on the third postoperative day and removed on the seventh postoperative day. The small crusts from the follicular units will fall off by themselves approximately 10 days after surgery, along with some implanted hair. Do not worry about the hair loss; the implants are still intact.

It is common for cysts to appear after the third month; these should be ruptured with a sterilized needle or forceps, and the scalp should be cleansed with antiseptic solution.

Hair growth will begin 90 to 120 days after surgery, and the final result will be visible within 6 to 8 months in men and within 10 to 12 months in women.

If a second implant procedure is necessary, this can be performed 1 year after the initial transplantation.

Surgical scars remain for an indefinite period and their quality is unpredictable, depending on characteristics of your skin.

Female Pattern Baldness

Although male pattern baldness is more prevalent, millions of women also experience hair loss. The most common cause of hair loss in women is androgenic alopecia, which usually occurs when an individual enters menopause. The operative technique for treating female pattern baldness is similar to that described for men, with a few modifications. Because women's hair is finer than that of men, we prefer to implant more minifollicular units containing three to four shafts rather than microunits with one or two shafts. We begin the replacement procedure in the posterior region and work forward toward the anterior region. When we need to implant grafts into the anterior hairline, we transplant microunits containing one or two hair shafts. Final results can be expected approximately 15 months after the procedure. Patients are advised not to color their hair until 1 month after surgery, because hair-coloring products can be abrasive to the newly implanted bulbs. If additional hair density is desired, a second replacement procedure can be performed 15 months later.

This 58-year-old woman presented with androgenic female baldness and was treated with one follicular unit replacement session. She is shown 14 months postoperatively.

This 62-year-old patient has typical temporal hair loss (*telogen effluvium*) as a result of an endoscopic brow lift. She is shown 11 months after transplantation of follicular unit micrografts.

Complications

The complications associated with hair transplantation are rare and minor compared with those of other techniques. The most common complication is forehead and eyelid edema, which appears 2 to 4 days postoperatively. Application of a 10% solution of boric acid dissolved in water or cool chamomile compresses can help reduce the swelling.

For patients at high risk for keloid scars, a trial procedure is recommended, during which approximately 10 follicular units are implanted. The donor and recipient sites are observed for 6 to 12 months to ascertain that the healing process is complete before proceeding with the full hair transplantation.

Temporary alopecia around a tight donor site closure (the telogen phase induced by ischemia) has been observed, but the hair usually regrows within 3 to 4 months. This is more likely to occur in patients who have scars from prior procedures.

Results

This young patient had incipient baldness; we increased his hair density. After 2 years, he enhanced his hairstyle with some blond highlights.

This 41-year-old patient with androgenic female baldness was treated with a single session of follicular unit implantation. She is shown 2 years postoperatively.

This 48-year-old man had hair loss and gray hair; he is shown initially at 15 months after transplantation. He is then seen 4 years postoperatively; he had changed his hair color to a slightly bluish cast.

This 48-year-old patient with a secondary frontal-glabellar lift was treated with follicular unit implantation. She is shown 3 years postoperatively with blond hair.

This 78-year-old man with white hair presented with hair loss. The newly implanted hair reframes his face, and he looks younger. He is shown 8 months postoperatively.

FUTURE DIRECTIONS

The Role of Platelet-Rich Plasma Growth Factors in Surgery for Male and Female Pattern Baldness

Baldness surgery with micrografts and minigrafts performed in megasessions was described in 1989 and 1991, and today it is a widely used technique for treating both male and female pattern baldness. The procedure transplants great quantities of follicular units harvested from the posterior occipital area of the scalp and places them in bald regions. These transplanted units carry a good genetic histologic structure, providing the future hair with the same quality of growth, durability, and characteristics as the donor area. Implanted hair growth has an individual cycle. During the first 2 weeks of implantation, the catagen phase occurs, marked by an inflammatory process in which redness in the scalp and shedding of the hair shaft is common. The patient then enters the telogen phase, which lasts between 3 and 4 months. This is followed by the latency period, which precedes the third phase, anagen. In this phase, the future hair begins to grow. During the resting period, substantial follicular unit loss can occur because of apoptosis. Between 15% and 30% of the implanted grafts will either be eliminated or absorbed by the scalp. Therefore only 70% to 85% of the implanted hair will sprout. Considering this important hair loss fact, we developed a clinical trial using platelet-rich plasma growth factors obtained from the patient's own plasma. This experimental research was submitted to and approved by the Ethics Committee of the Pontificia Universidade Católica do Rio Grande do Sul in Brazil, Division of Plastic Surgery.

Platelet Growth Factors and Hair Stem Cells

The first articles on growth factors derived from plasma were published during the 1970s and 1980s describing their application for tissue repair and hemostasis during the healing process of ulcers and undermined wound surfaces. More recent works in orthopedics and odontology demonstrated the role of such factors in bone graft recomposition and in the osteosynthesis of teeth. Man et al in 2001 and Bhanot and Alex in 2002 reported new applications of platelet-rich plasma in the wound sites of cosmetic procedures. The growth factors contained in platelets of blood plasma are basically three: platelet-derived growth factor (PDGF), transforming growth fac-

tor (TGF), and vascular endothelial growth factor (VEGF). These are protein molecules that, in contact with their respective receptors, act in tissue angiogenesis, stimulating the healing and growth of new organic structures. The action of growth factors on the germinative hair cycle has already been studied in both its embryologic and adult phases; however, it has not yet been studied in hair micrograft implantation surgery. No clinical trial or experimental protocol had previously been performed to verify the efficacy of those factors in the growth and density of implanted follicular units.

This illustration depicts follicular units being implanted and the associated platelet plasma growth factors, showing the dystrophic shading phase and the new proliferative phase with an intense vascular endoneogenesis supporting the new hair development to the anagen phase. There is an intense growth factor migration into the stem cells in the bulge area.

These growth factors interact in the bulge area with cells of the matrix, thus activating the proliferative phase of the hair. Stem cells are more primitive and of ectodermal origin. They give rise to epidermal cells and sebaceous glands. Germinative cells of the matrix, which are found at the dermal papilla, are of mesenchymal origin.

The hair follicle cycle shows the meeting between matricial cells from the papilla and the stem cells in the bulge area, starting the growing phase of the new hair follicle.

Both cells need each other, and when they meet through the action of various growth factors (PDGF, TGF, and VEGF), they give rise to the future follicular unit, which consists of the hair shaft, sebaceous glands, erector pilus muscle, and the perifolliculum. Headington described this histologic unit in 1984. It is the complete and developed follicular structure in the anagen hair cycle phase that lasts from 3 to 6 years in the scalp.

Experimental Model

Twenty male patients aged 22 to 54 years with male pattern baldness in the frontal, parietal, or occipital area were selected for this experiment.

Two symmetrical 2.5 cm² bald areas were delineated. On the right side of the patient's head, follicular units imbued with platelet plasma growth factors were implanted; on the left side, standard follicular units were implanted as a control. In all

patients, both areas were implanted with an equal number of micrografts. All patients were duly informed about the clinical trial and signed informed consent documents. This patient is shown 7 months after implantation, with improved hair growth on the right side.

Surgical Technique

Harvesting of Follicular Units

In all cases, a hair-bearing ellipse flap was taken from the occipital area of the scalp above the neck, where the best histologic and genetic quality of hair is present. The flap size varied according to the amount of follicular units needed. For medium-type baldness, an ellipse was obtained, usually 15 cm long by 2 cm wide, from which 1200 follicular units could be obtained.

The donor area was closed without tension, using an intradermal or continuous suture, to enable a secondary harvesting of grafts 3 to 4 years later if needed. Two groups of 180 follicular units were harvested and prepared—one group was imbibed with platelet plasma growth factors and the other was kept wet with saline solution on an acrylic surface.

Obtaining the Platelet Plasma Growth Factors

Before surgery, 80 ml of blood was withdrawn from the patient in eight vacuum flasks, with each one containing 1 ml of anticoagulant, 3.2% trisodium citrate (Vacurette; Greiner Bio-One, Kremsmuenster, Austria).

The eight flasks were centrifuged at 1000 rpm for 10 minutes. This slow speed is important so that platelets are not displaced to the bottom of the flasks. The plasma was then dispensed into four new flasks for a second centrifugation at 5000 rpm for 10 minutes. The floating platelet-poor plasma was discharged, leaving only 2 ml of concentrate—the platelet-rich plasma with four to six times more platelets than normal plasma, and therefore containing a high concentration of growth factors. This concentrate was then added to the follicular units before implantation. The follicular units were kept in the platelet growth factor solution for 15 minutes to allow the growth factors to attach to the stem cells located in the bulge area of each follicular unit.

Next, 10 drops of 10% calcium chloride was added to the mixture to convert fibrinogen into fibrin, thereby producing the plasmatic gel that would seal the growth factors around the micrografts. The follicular units were then ready to be implanted.

Implanting the Follicular Units

The entire bald area on the scalp was massively infiltrated with saline solution containing epinephrine 1:160,000. This tumescent technique, or “scalp ballooning,” with the vasoconstriction obtained with the epinephrine injection, helps to limit bleeding and facilitates implantation of the micrografts.

The units were implanted by the stick-and-place punctiform technique. In the outlined area to the right, the units imbued in platelet-rich plasma growth factors were implanted; to the left, the units considered controls were placed. The same number of grafts was implanted on both sides, thus allowing greater control for the clinical trial.

For this procedure, microblades (BD Beaver) and lance tip 15DEG (Ellis Instruments) and jeweler-type microforceps were used. After the two demarcated areas were implanted, the remaining bald area was implanted using standard follicular units. Moist gauze was applied to the implanted area and secured by an elastic bandage that was kept in place for 24 hours. After that time, the patient removed the bandage and washed the entire implanted area with an antiseptic, neutral shampoo.

Endpoint Evaluation

All patients were evaluated monthly for 7 months, and the yield of follicular units was counted in the outlined areas. An accurate inspection, counting the number of follicular units within the two areas, was performed by staining four india ink spots. The final count was performed at the end of 7 months with a magnifying glass by the surgeon; the hairs were recounted by two assistants for confirmation.

This 38-year-old patient had 150 implanted follicular units. After 7 months, 114 were counted on the right and 95 on the left—an improvement of 20% for the platelet plasma growth factor-imbibed side.

Statistical Analysis

The data were summarized using mean standard deviation. To compare the platelet-rich plasma growth factor protocol and the control group, the paired *t* test was used, because data showed a gaussian distribution. Analyses were performed using SPSS version 12.0 (SPSS, Chicago). The significance level was set at 0.05.

Patient Characteristics, Implanted and Yield of Follicular Units per 2.5 cm² Areas, and Normal and Rich Plasma Platelets (N = 20)

Age (yr)	Region of Baldness	Implanted Follicular Units	Yield of Follicular Units		Platelets	
			Control	Experimental	Normal Plasma	Rich Plasma
35	F	138	117	135	224.000	460.000
45	F	170	129	134	185.000	417.000

38 ± 9	—	142 ± 17	102 ± 14	117 ± 15	206.800 ± 44.942	528.250 ± 243.586

Data are summarized as mean ± standard deviation. F, Frontal; O, occipital; P, parietal.

Experimental Results

There was a statistically significant difference observed in the yield of follicular units when the two groups were compared ($p < 0.001$). The experimental group with the platelet-rich plasma growth factor showed a density of 18.7 follicular units per cm^2 , whereas the control group showed 16.4 follicular units per cm^2 . The difference of 2.3 follicular units per cm^2 (95% confidence interval, 1.6 to 3.2 follicular units per cm^2) represented a 15.1% increase in the yield of follicular unit density between the two groups.

Group	Yield of Follicular Units	Effect/ cm^2	95% CI	p (Student t)
Implanted	22.7	—	—	—
Experimental	18.7 ± 2.4	2.4	1.6 to 3.1	<0.001
Control	16.4 ± 2.2	—	—	—

This graph shows the total implanted follicular units and the yield of follicular units for both experimental and control groups. This means that if there is a 100 cm^2 (10 by 10 cm) bald area to be implanted, one can obtain 240 follicular units more, or approximately 480 hair shafts, assuming two shafts per follicular unit. It is important to note that some patients had only a 3% increase using the platelet-rich plasma growth factor protocol, whereas others had a 52% increase in follicular unit density.

This 32-year-old patient had 125 follicular units implanted on each side; 117 follicular units were counted on the right and 93 on the left; thus 26% more hair was noted in the area implanted with platelet-rich plasma growth factors. Software image analysis demonstrated a similar density of 28% on the right side.

This 78-year-old woman had female pattern baldness and was treated with follicular unit grafts and platelet growth factors. She is shown 14 months postoperatively.

This 62-year-old man had very thin hair. He was treated with platelet-rich growth factor follicular unit grafts and is shown 1 year postoperatively.

This 54-year-old patient had very thin hair and was treated with platelet-rich growth factor follicular unit grafts. He is shown 14 months postoperatively.

This 36-year-old patient had poor hair growth after one replacement procedure. The results are shown after a second micrografting procedure with platelet-rich growth factor follicular unit grafts. At 1 year postoperatively, there is approximately a 55% increase in hair follicles.

Imaging

The use of digital imaging is an important comparative tool for assessing density. For one patient, a digital camera (5.0-megapixel, 24-bit color) was used at a fixed distance from the scalp. Photographs in this study were recorded in raw format. Image-Pro Plus 4.5 image analysis software (Media Cybernetics) was used to perform morphometric analysis and to derive objective measures of the hair color density from the marked areas on the right and left sides. A color threshold level was selected interactively by an experienced observer and applied on both images from each patient. The scale used was 40 pixels/cm. The area covered by hair was divided by the total area measured on every image. The patient shown on p. 683 demonstrates 28% more density on the right side. By counting the follicular units with a magnifying glass, an increase of 26% was observed in that area. This indicates that both systems are practically the same and that the digital program could perhaps be improved in future studies.

Concluding Thoughts

In this clinical trial of 20 patients with male pattern baldness, there was 15.1% more hair yield in follicular units and density in the areas treated by platelet-rich plasma growth factors. This new development for hair transplant surgery demonstrates that the use of autologous platelet growth factors can improve capillary density with low cost and low morbidity, using a simple technique—a significant improvement over conventional techniques. Especially for patients with less density and very thin hair in the donor area, this technique should be a great contribution. Although these results are significant, further research, such as a double-blind test, should be performed to evaluate the final results with outside assistance, in asymmetrical areas. This offers a new perspective on hair transplantation and is an important contribution to implantation surgery with follicular unit megasessions.

Clinical Caveats

Careful patient selection and good patient communication are crucial to achieving optimal results.

Surgeons should always be honest when discussing the positive and negative aspects of hair replacement with patients. It is especially important to make the patient aware that a second procedure may be necessary to maintain the new hairline.

Hair follicles are harvested from the posterior cervical area where the hair density is greatest and the quality is best. This is normally 6 to 8 cm from the nape of the neck.

A well-trained team is a requisite for a good result.

Scalp ballooning tumescent technique is important to prevent bleeding during surgery and to maintain the grafts inside the punctiform incision.

Scalp ballooning at the donor site makes the separation of the follicular units easier and reduces bleeding in this area.

The surgeon should avoid division of the sensitive branches in the donor region to prevent posterior paresthesias or painful processes that can last for months.

The scalp does not tolerate stretching, so closure of the donor site must be done gently.

When preparing the grafts, it is important not to cut the epidermis.

We recommend implanting a maximum of 1500 follicular units per procedure.

CHAPTER 21

Reoperation, Refinement, and Treatment of Complications After Hair Transplantation

JACK FISHER

Hair transplantation is one of the most frequently performed aesthetic surgery procedures in men today. The goal is hair restoration that is natural and virtually imperceptible. A poorly designed or executed procedure will result in a highly visible and unnatural hairline. Despite its popularity, this procedure often results in unsatisfactory aesthetic outcomes. The causes of these problems and solutions for addressing them are the focus of this chapter.

Before defining the problems that create bad results in hair transplantation, one must identify the components of a natural hairline. Without knowledge of what defines the normal, it is difficult to discuss the abnormal. A successful hair transplant should look totally natural, with a hairline that is irregular, feathered, and age appropriate.

When considering a patient for hair transplantation, the surgeon must realize that hair loss is progressive. Probably no single factor is as important or has led to so many poor results as when the progressive nature of hair loss is ignored. The location of the frontal hairline is another key factor. What looks good in an 18-year-old male will usually not be appealing in a 45-year-old. Therefore it is important to design a frontal hairline that will be aesthetically acceptable over a long period as the patient's face matures and hair loss continues. High hairlines rarely look bad, but extremely low hairlines can be a disaster. One of the most critical anatomic components of a natural hairline is the frontotemporal angle. Rounding off this angle with hair transplants usually leads to a bizarre appearance, especially as the patient ages.

Aesthetic surgeons frequently place a high premium on obtaining symmetrical results in most procedures. However, in hair transplantation, a perfectly straight, symmetrical hairline, even with the use of micrografts, is destined to look artificial, as can be seen in this patient, who had a large number of transplants placed in an extremely straight line. Irregularity and asymmetry are the hallmarks of a natural-appearing hairline.

Common Problems Requiring Reoperation

Unsuccessful hair transplants generally share similar characteristics:

- The hairline is too even and straight.
- The frontotemporal angle has been blunted.
- Large plug grafts have been used.
- The transplanted hair fails to grow.
- The hairline is too low.
- The hair has been transplanted at an incorrect angle.

Transplants done with large plug grafts represent a major problem. Unfortunately, many individuals have undergone these procedures over the past three decades. Careful analysis is required to correct or improve these difficult cases. Often there is significant scarring in the donor site, because a coring device was used to remove grafts containing 10 to 40 hairs at a time. Frequently the donor site was allowed to heal by secondary intention, resulting in significant scarring. Many of these patients have little if any available donor hair remaining for further grafting.

In individuals with adequate donor hair, a significant improvement can be achieved by excising the old plugs, recutting and recycling this hair, and using small one- to three-hair grafts for further transplantation. This improvement can only be accomplished, however, if sufficient residual donor hair is available. Scalp excisions and forehead advancement procedures are important adjuncts in these difficult secondary cases.

Another problem is the failure of transplanted grafts to take. In healthy patients, the graft-take rate should exceed 90%. Small one- to three-hair grafts, properly created, will rapidly undergo neovascularization, and in a healthy patient most of this hair should grow. However, if the grafts are poorly prepared, the success rate falls off drastically. It takes a considerable amount of time and experience for a surgeon to be able to create these small grafts, and a well-trained team is critical for a successful outcome.

One of the most difficult problems to correct successfully is a hairline that has been placed too low. As the patient ages, the hair recedes, leaving a bizarre, isolated frontal hairline. Often the only solution is an aggressive procedure that involves resection of these grafts combined with a forehead lift with regrafting.

Finally, there is the group of patients who have had cosmetic surgery and experienced secondary hair loss, such as after a face lift or a coronal brow lift. In a patient who has undergone a face lift, temporal hair loss is the most common; it is caused either by excess skin tension or superficial undermining with direct damage to the hair bulbs. Hair loss is usually related to tissue ischemia. In many of these patients, the hair will regrow after 6 to 9 months, and a conservative approach is best. In some individuals the hair fails to regrow, and transplantation is an ideal solution. Traumatic alopecia, which usually occurs from hair bulb ischemia, may be caused by factors other than cosmetic surgery. Prolonged pressure on the scalp, such as in a comatose patient, can also lead to hair loss without ischemia of the scalp. The skin is more tolerant of ischemia than the hair bulbs are.

Evolution of Technique

In 1959 Orentreich published a landmark report on the use of punch grafts to treat male pattern baldness, thereby establishing punch grafts as the standard treatment for almost three decades. Although results achieved with this technique may have been reasonable at that time, the abnormal cornrow appearance they produced was far from aesthetic. These grafts were harvested with a 3.5 to 5.0 mm punch, producing plugs containing a large number of hairs. This technique created two major problems: (1) a severely scarred donor site in the posterior scalp because the donor holes were allowed to heal by secondary intention, and (2) an unnatural recipient site with the classic cornrow appearance.

Eventually, smaller plugs containing six to eight hairs were used, but this still resulted in an unnatural appearance. It was not until the early 1990s that physicians began to recognize that donor grafts containing the follicular units (naturally occurring clusters in which hair grows) of one to three hairs were the key to producing

natural results. By transplanting the hair in these smaller units, the cornrow appearance is avoided.

The other great advance in the evolution of hair transplantation occurred with the development of the technique for transplanting large numbers of hairs in one session. Pioneers such as Carlos Uebel and others developed techniques whereby 1000 to 2000 follicular units could be transferred at one time. Thus the combination of small grafts composed of anatomically correct one- to three-hair units and the ability to rapidly transfer a large number of grafts in a single “megasession” produced a revolution in hair transplantation.

Indications and Contraindications

The patient’s age, family history of hair loss, current hair pattern, amount of hair remaining, and expectations are all important factors in selecting potential candidates for reoperative hair transplantation. Patients with minimal hair loss are the best candidates for primary—and in particular secondary—hair transplantation procedures and are much more likely to be satisfied after hair transplantation.

Patients in their late or early twenties and those in their teens are rarely appropriate candidates. These young patients often develop a receding hairline later in life and may wish to fill in the anterior hairline they previously had. Such a procedure is usually a major mistake, because with progressive hair loss the patient will be left with an isolated frontal fringe with balding areas behind the transplanted rows. An attempt to create a juvenile hairline by rounding off the temporal recession is also a mistake in a young patient. Patients who demand an inappropriate hairline should be excluded from surgery; otherwise, both the patient and the doctor at some time in the future will regret the procedure.

This patient had plug grafts to thicken his frontal hairline in his early twenties. As the hair surrounding the unsightly plugs fell out with aging, the large plug grafts became exposed, creating this noticeable deformity.

Another common problem when a young patient undergoes a hair transplantation procedure at too early an age is the creation of a permanent frontal fringe with extensive baldness behind it. The use of large plug grafts makes the deformity even more noticeable. However, in this patient, even if small natural grafts had been inserted originally, the effect would still look unnatural because of the extensive baldness that evolved over the years behind the grafts. The major point demonstrated by this case is not to perform transplantations too early.

A patient with extensive hair loss with only a thin posterior and lateral remaining fringe is also a poor candidate for reoperative hair transplantation. Such a patient can be given a frontal hairline, but if complete coverage of the area of alopecia is the goal, the patient will likely be disappointed after the procedure. Caution should also be exercised when attempting hair transplantation in the occipital area. In young patients or those with extensive hair loss, overly aggressive transplantation in this region can lead to a strange “halo” pattern, with a permanent tuft of central occipital hair surrounded by a bald ring or halo that progresses as the patient ages and hair recedes. It is important to explain to the patient the possible ramifications of overly aggressive hair transplantation in this area. Thus in younger patients it is prudent to graft the frontal and superior regions of hair loss initially and to observe over time the evolution of the patient’s hair loss. If a young patient with fairly extensive hair loss rejects a high hairline with temporal recession, this patient is not a good candidate for transplantation.

As in all aesthetic surgery procedures, it is essential that the patient be fully informed to ensure ultimate patient satisfaction. This is even more important in an unhappy patient who has had a poor result and wants revision. Realistic expectations must be established before the surgeon considers reoperating on such patients, based on the results of previous surgery and what available donor hair tissue remains. The patient with a poor result from 20 years ago who expects a miracle should be excluded from surgery. Some of these patients must resign themselves to wearing a hairpiece

to cover up either a poor result in the recipient area or to cover excessive scarring in the donor site from previous punch grafting. In other areas of cosmetic surgery, such as a face lift, the procedure can be repeated over time. However, a patient with male pattern baldness has limited donor hair; therefore it is critical to set appropriate goals with the patient based on this simple anatomic fact.

Preoperative Assessment

Preoperative assessment focuses on the recipient site to evaluate the results of the transplantation, as well as the donor site to assess residual scarring and the amount of available donor hair. The recipient site should be examined to determine whether the hairline was placed in the correct location—not too high or too low—and whether it was properly created. That means it has an irregular line with a natural temporal recession. A common problem after hair transplantation, especially in the past, was creation of a straight hairline. Hairlines need to be irregular; even a properly located hairline with small grafts in the correct location will look unnatural if it is perfectly straight.

After assessing the recipient area, the physician must critically evaluate the potential donor site if further grafting is to be considered. Initially, donor grafts were harvested with punches, and the residual donor area was allowed to heal by secondary intention, creating a significant amount of scar tissue. Eventually, physicians began to use linear excision of the donor site with primary closure. This became the standard, which significantly reduced scarring in the donor area. Unfortunately, in the past and even today, some surgeons make multiple parallel incisions each time they harvest donor hair, which results in multiple transverse scars in the posterior recipient area. This technique is rarely necessary. Most patients can undergo at least two or three repeat procedures over time using a single donor site and creating a single scar. If multiple transverse parallel donor scars are too close together, further excisions run the risk of tissue devascularization and scalp necrosis.

The course of hair loss should also be considered. Hair loss is both progressive and unpredictable. It is this unpredictability that is the single most important issue in evaluating patients as candidates for these procedures. In designing the hair pattern to be transplanted, the surgeon must take into consideration the patient's progressive postoperative hair loss over the ensuing decades.

The individual characteristics of the patient's hair and skin color must also be examined. The less the contrast between skin and hair color, the more natural the final result will appear after transplantation. Thus light hair with fair skin or dark hair with dark skin will have a low contrast. Dark hair on light skin, however, has a high contrast, and grafts with several hairs will look more unnatural in these high-contrast patients.

The phenomenon called *compression* is particularly noticeable in patients with a high-contrast situation. Compression is a condition in which there are too many hairs exiting a single hole, thereby creating a “bouquet” appearance, with the hair spreading out distally from a central site. To avoid compression of individual grafts, it is particularly important to use small micrografts or follicular units in dark-haired patients. The texture, density, and straightness versus curliness of the hair should also be assessed. Curly hair provides better coverage of the scalp than straight hair after transplantation. Fine hair gives less coverage than thick hair.

Preoperative Planning

In secondary hair transplantation, as in other types of revision surgery, planning is as important as the execution of the surgery itself. In patients with adequate donor hair who had previous unnatural-looking plug grafts, a two-step procedure is suggested. First, the plug grafts are excised, recut, and replanted as small, natural-looking grafts; then donor hair is harvested from the posterior scalp and implanted as small follicular units in between the previous plug grafts to fill in the spaces.

There is no consistent pattern to follow when planning incisions in this group of patients. When large, unsightly grafts are visible, they need to be excised, and wherever there is residual donor hair, it needs to be harvested. For more extensive cases, a more aggressive approach may be necessary, with radical excision of the previous recipient plugs, followed by secondary grafting. Badly scarred donor areas can be improved in selected patients as long as there is adequate hair in the area to cover up scarring from further excisions. Wide donor scars can frequently be improved by simple reexcision with primary closure. In more extensive cases, tissue expansion or flap rotations can be used to improve unsightly donor scars.

The goal of reoperative hair transplantation is to produce an overall hairline that is both natural and undetectable. Therefore, when planning revision surgery, the surgeon should avoid placing the transplanted hair too low and rounding off the temporal recession. The emphasis should be on creating a high hairline at least 8 to 10 cm above the glabella with a natural-appearing frontotemporal angle.

Proper angulation or direction of the transplanted hair is another key anatomic factor in producing a natural result. Hair grows at different angles at different locations on the scalp. Along the frontal hairline, the hair should be angled in a slightly anterior direction. Too much anterior angulation appears abnormal, as does posterior angulation. Hair in the temporal area needs to be angled downward, whereas hair on top is directed straight upward and hair in the posterior scalp is directed downward. Incorrectly angled hair requires revision surgery.

In this case, hair was transplanted along the patient's right frontal hairline at the wrong angle. Even though the grafts were small and natural appearing, because of their incorrect angulation, they created a strange appearance. This patient requested correction, which required excision of the scalp in the area marked by the ellipse. After this area healed, grafts were inserted at the correct angle, solving the problem.

This patient's hair grafts were inserted at too acute an angle. The hairs are growing straight forward from the scalp, yielding a very unnatural appearance. To correct this problem, excision, recycling, and new grafting were all required.

Options for Reoperative Hair Transplantation

There is no single operation for management of poor results or complications from previous hair transplantation. Management of these complex cases requires a combination of techniques. In some cases, simple excision of unsightly plugs alone can yield a reasonable improvement, especially in a patient who wishes no further grafting procedures or one who no longer has any usable donor hairs.

However, in most patients with unsightly plugs, it is necessary to excise the plugs and recut and recycle them as small follicular units or micrografts. Excision of old plugs is performed under loupe magnification ($2.5\times$ or $3.5\times$) using a No. 11 blade or a 1 or 2 mm biopsy punch. It is important to keep the tip of the blade parallel with the hair shaft and follicle to avoid injury to the entire hair unit. Improper angulation of the knife blade will damage the follicle or may leave it in its original location, only to regrow another unsightly plug. Once the entire plug is removed, it is carefully recut into small individual units for regrafting. Typically, only 50% to 75% of the hairs removed in the old plugs can be made into new, acceptable small grafts because of scarring. However, in patients with limited donor hair, every hair counts. The best solution is to combine this technique with further harvesting of posterior scalp donor hair to create more small grafts for filling in between previous grafts.

Partial plug removal

Plugs removed to be recycled into minigrafts

Additional micrografts and minigrafts

Immediate postoperative result

Patients with unnatural hairlines may present special problems, such as improper angulation of the original grafts, or hairlines placed too low, too high, or too straight. Again, a proper preoperative evaluation is critical, depending on which of these four problems is present. In a patient with improper angulation of previous grafts, simply filling in between with new grafts will not solve the problem. These grafts must be excised carefully, as previously discussed; regrafting of the entire area is the best solution using both the old recut grafts along with new ones. In patients whose hairlines are too low, more aggressive treatment may require scalp excision and a forehead lift in addition to plug excision and graft recycling. In patients whose hairlines are too high, more aggressive treatment may require scalp excision and a forehead lift in addition to plug excision and graft recycling. In patients whose hairlines are too straight, more aggressive treatment may require scalp excision and a forehead lift in addition to plug excision and graft recycling.

Avoiding Donor Site Problems in Patients With Previous Transplant Procedures

The tension in the donor site closure should be minimized.

Scalp elasticity should be evaluated in patients with multiple donor site scars.

The closer the previous scars are to the lower neck hairline, the better the elasticity, because it is possible to recruit neck skin.

The higher the previous donor site scars and the closer to the fixed occipital scalp, the less elasticity will be available. This makes further donor site excisions more difficult to close.

Patients who had previous plug grafts harvested from the donor area have stiffer donor tissue, making closure of strip excisions more difficult.

Multiple previous transverse strip excision donor sites should be noted because of the risk of tissue devascularization associated with further harvesting of donor tissue.

Patient Examples

Cornrow Plugs

This patient presented with noticeable plug grafts along the hairline. Because the patient had a high-contrast component with dark hair and light skin, the plugs seemed even more obvious. Correction of this common problem was accomplished using three different techniques. First, the old plugs along the outer edge were excised as previously described; next these plugs were cut into small follicular units to be re-inserted. At the same time, an ellipse of posterior scalp measuring 1.8 cm wide and

16 cm long was excised and cut into 1200 follicular units. These small grafts plus those that were recycled were then placed between and in front of the remaining plugs. The excised plug sites, which usually measure 5 to 6 mm in diameter, are closed with a single 5-0 nylon suture that is left in for approximately 1 week. At 1 year postoperatively, the patient is healed and has had complete correction of the artificial plug look. The results here demonstrate that hair transplants should not be recognizable but should resemble natural hair.

Isolated Frontal Forelock

Some patients develop an isolated frontal forelock as they age. When connecting this forelock with the hair posteriorly, it is important not to drop the hairline too low. It may be necessary to begin transplanting behind the frontal forelock.

This patient demonstrates the appearance of an isolated frontal forelock. He has two isolated tufts of hair on his head, creating a bizarre, unnatural appearance. To correct this problem, a single session of 1500 follicular grafts was used to connect the two isolated forelocks with the hair posteriorly. This approach produced improved framing of the face and a much more normal appearance to the hairline. Also, the hair was placed in an irregular pattern, which produced a more natural appearance.

Temporal Alley Defect

In patients who have had previous transplants along the superior scalp and occipital area, a gap or “alley” may develop as the hair recedes inferiorly along the sides of the head. In this situation, a combination of procedures is required, including excision of the scalp as well as further grafting.

A common problem after scalp excision, however, is the phenomenon of “stretch back.” This refers to the progressive widening over time of the excised area as a result of tissue relaxation.

This patient presented with a temporal alley defect after an unsuccessful attempt at hair transplantation.

The defect was excised and a hole was created for the Mitek suture fixation device, which was placed on either side of the defect.

The sutures were then crisscrossed to pull the edges of the defect together, thereby reducing the amount of stretch.

At a separate session 4 months later, approximately 1200 follicular grafts were placed in the area, completing the restoration and significantly improving the appearance in the temporal area.

Abnormally Low Hairline

One of the most difficult problems to correct is a hairline that has been placed too low, especially if unsightly plugs were used. In this situation, the old plugs must be carefully excised and recut into small grafts. Scalp excision and forehead lift may also be required. In these complex cases, multiple stages are frequently required.

Correction of a Low Hairline: Operative Overview

1. The frontal hairline scalp, including the old unsightly plugs, is excised as a circum-linear ellipse.
2. The galea is left intact and the ellipse of skin with its old plug grafts is recycled, as described earlier, creating new, small, one- to two-hair grafts for replanting.
3. Next, a forehead lift is performed while the excised hair is being recut.
4. Unlike a traditional forehead lift, in which the goal is elevation of the eyebrows and upper lids, this forehead lift advances the forehead skin superiorly to raise the new future hairline, leaving the eyebrows alone. This is accomplished by not dissecting below the superior orbital ridges and releasing these tissues.
5. The frontal forehead is stretched superiorly by making numerous parallel, horizontal releases in the periosteum in a subperiosteal dissection or in the galea in a subcutaneous dissection.
6. Next, deep sutures of 3-0 Ethibond are used with the Mitek fixation device, outer table drill holes, or the Endotine device (Coapt Systems, Inc.) to fix the forehead in an elevated position. (I have used all three techniques with excellent results.)
7. The suture fixation device is placed several centimeters above the new future hairline to allow maximal elevation while it is being tied.
8. Once the forehead has been adequately elevated along its superior aspect, the skin is closed with 3-0 Vicryl sutures and a running 3-0 or 4-0 Monocryl suture.
9. The old plugs, which have been recut into small grafts, are now reinserted behind the suture line.
10. After the skin is adequately healed in 3 to 4 months, large-volume grafting is begun to create a new, natural hairline.

This patient presented with an abnormally transplanted hairline, with the grafts placed too low in the temporal region. Besides the original transplanted hairline being too low, the grafts had also been placed incorrectly in a curved line so that the temporal area was rounded off, thus losing a normal frontotemporal angle.

A more aggressive approach was required for this revision. A radical excision of the previous plug grafts was done, along with excision of a segment of scalp along the frontal and temporal areas. Holes were then made at multiple sites for insertion of Mitek devices.

The Mitek device with 2-0 Ethibond sutures attached was inserted. The sutures were tied with significant elevation of the forehead in both the midline and the temporal area. The incision was allowed to heal for several months, and then the patient underwent micrografting to the area.

Postoperatively a significant elevation of the forehead is evident, with creation of a normal frontotemporal angle. The patient has a visible scar in the temporal area from the forehead lift. However, this scar could not be avoided, because further grafting in this area would have recreated the abnormal appearance.

High Hairline

In males, hairlines that are too high are rarely a problem, and as long as donor hair is available, further sessions of grafting, using small grafts with an appropriate irregular hairline, solve these patients' problems. However, in females who had an overly aggressive forehead lift, a high hairline can create an abnormal appearance, especially if it also creates a masculinizing acute temporal recession.

Straight Hairline

Another problem that presents a reoperative challenge is a transplanted hairline that is extremely straight. Hairlines need to be irregular; even in patients with small grafts, straight hairlines are noticeable. Obviously, if the straight hairline includes unsightly plugs, these must be excised and recycled, as previously described. In many of these patients, as long as the hairline is not too low, it can be improved by placing small one- to two-hair grafts in an irregular pattern in front of the previously grafted areas. It is easier to improve the hairline in patients with light skin and light-colored hair, because the color contrast is less obvious than in patients with dark hair and light skin. In high-contrast patients with dark hair and light skin or light hair and dark skin, a greater number of grafts will be required to mask the previous procedure and create irregularity. This is true for all corrective procedures. Color contrast is a subtle but important issue when performing secondary hair restorations.

Traumatic Hair Loss

One of the most common causes of traumatic hair loss is aesthetic facial surgery. This can be caused either by direct damage of the follicles from superficial elevation of the skin flaps or by excessive tension leading to ischemia. The skin may not visibly show signs of ischemia after aesthetic surgery, but there may be enough relative decrease in tissue perfusion to damage the follicles. In most patients, the hair regrows after 4 to 6 months, but in some cases the hair loss is permanent.

In some patients, simple excision of the non-hair-bearing scar can be successful. However, this maneuver often fails, because the new scar may also lose its hair, and reexcision, because of the risk of undue tension, will lead to ischemia and further hair loss. For these reasons, many patients with traumatic hair loss require hair transplantation to fill in the defect. Remarkably, small hair transplants placed directly into scar tissue consistently grow. The problem with placing small grafts into scar tissue is mechanical. Unlike normal scalp, which is relatively thick, areas of hair loss with or without scar tissue are frequently thin, and it can be difficult to insert the grafts in these areas. Using a tumescent technique in the recipient areas is particularly helpful in this situation. The tumescent fluid creates the depth necessary for graft insertion. In some of these patients the grafts cannot be placed as close together, because the scar is thin and relatively ischemic. In these patients several sessions performed over a period of time may be more useful.

Most patients with traumatic hair loss have their hair restored in two sessions of grafting. Combining excision with grafting may be the ideal situation, because excising a portion of the non-hair-bearing area produces a smaller area requiring grafting. When combining these two procedures, the surgeon should excise the skin conservatively, because further tension and ischemia will lead to more hair loss and may create a relatively hypoxic environment in which few of the transplanted grafts survive.

One of the benefits of today's micrografts or follicular grafts is their high success rate. These small grafts have fewer metabolic demands than the larger grafts previously used and usually do well in areas of scar tissue and even in skin grafts. The older-style plugs, especially those with 10 to 20 hairs in each plug site, had less tolerance for ischemia. Frequently, patients with old plugs have sites or areas within the plugs with poor hair growth. One also sees scars from the old plugs creating a "cobblestone" appearance, with little or no hair growth. This occurs because the skin of the plug graft was neovascularized and survived, but the follicles within never successfully grew hair. This cobblestone look is unsightly, and excision of the non-hair-bearing skin plugs is frequently the best solution, followed by further grafting when possible.

This woman had posttraumatic hair loss in both the preauricular temporal area and the posterior neck–postauricular area after a face lift. In one session, 350 grafts were placed in the temporal area and 400 in the posterior neck–postauricular area. Care was taken to properly angulate the hair grafts; this maneuver is essential to achieving a natural result. In the temporal area, hair naturally grows in a downward and slightly posterior direction. In the posterior neck, the hair needs to grow downward and slightly backward. Following these guidelines, significant improvement can be achieved in a patient with traumatic hair loss after aesthetic surgery.

Postoperative Care

Of all the areas of aesthetic surgery, hair transplantation, whether primary or secondary, is one of the easiest procedures to deal with in the postoperative period. Every physician has his or her own protocols. I put patients in a protective head dressing, similar to a face-lift dressing, for 24 hours and then remove it. Where there is a donor site closure with sutures, the patient washes this area in a normal manner. Where the grafts have been inserted, I instruct patients that after the first 24 hours, they should blot a mild shampoo on the recipient site once a day and rinse the area using a cup, avoiding a direct shower stream hitting the recipient grafts. After 6 days patients can wash the recipient areas without any restrictions, since the small grafts are well fixed at this time. I usually leave sutures in for 10 to 12 days in the linear donor site area and where the forehead lift has been performed because of significant tension. Otherwise, nothing unique is required in the immediate postoperative period for management of these patients.

Concluding Thoughts

Many factors go into creating a successful hair transplant. Avoiding complications before they occur is obviously the optimal situation. Many of the problems associated with less than satisfactory results after hair transplantation are more often associated with mistakes in judgment and less likely the result of errors in surgical technique. To avoid an unnatural result, the surgeon must realize that hair loss is progressive in nature. It is important to design a hairline that will be aesthetically acceptable over time as the patient matures and hair loss continues.

Clinical Caveats

The following four characteristics are associated with unsuccessful hair transplantation: (1) large, unnatural plug grafts, (2) an extremely straight hairline, (3) a blunted frontotemporal angle, and (4) a hairline that is too low.

Surgical correction of large, unnatural plug grafts requires graft excision, recutting into individual one- and two-hair grafts, reimplantation of new small grafts, and closure of individual donor sites with single small sutures.

Surgical correction of a hairline that is too straight involves removal of periodic grafts along the hairline if plugs are present, with recycling farther back, and use of small single-hair grafts to create a feathered, irregular hairline.

Surgical correction of a blunted frontotemporal angle includes removal of hair grafts and elevation of the temporal skin, with advancement superiorly and posteriorly.

Surgical correction of an abnormally low transplanted hairline requires excision of frontal grafts, with reimplantation farther back, excision of skin along the transplanted hairline, and a forehead lift and closure of the defect.

Color contrast is a subtle but important consideration when performing secondary hair restorations.

PART V

BROW LIFT

This page intentionally left blank

CHAPTER 22

Clinical Decision-Making in Brow Lift

FOAD NAHAI

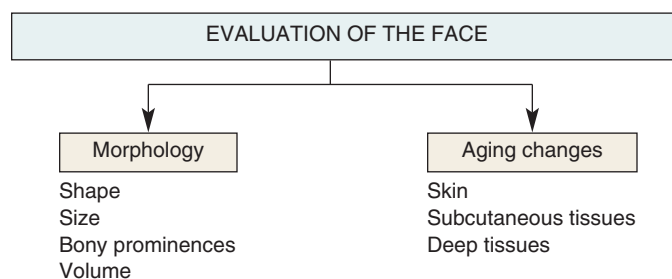

Evaluation

We evaluate the entire face rather than isolated zones. The hallmark of a youthful face is the smooth transition from zone to zone; for example, brow to eyelid, eyelid to cheek, cheek to perioral area, perioral area to jawline, jawline to neck. For best results, procedures are planned to rejuvenate all of these areas and to restore a harmonious transition from zone to zone.

It comes as a surprise for a patient seeking an “eyelid lift” to be advised that in addition to blepharoplasty, a brow lift is also recommended. Most patients will accept the surgeon’s recommendation, yet others resist, saying they only want to remove the excess skin or bags from their eyelids. For some it becomes a financial consideration, with concerns that each added procedure will increase the cost. Regardless, we explain to the patient that regional or full facial rejuvenation would be the best option rather than localized, isolated procedures. We leave the final decision to the patient.

In my practice, an isolated brow lift is a rarity. I consider a brow lift to be one component of periorbital rejuvenation, encompassing the brow, upper and lower eyelids, lid-cheek junction, and midface. No brow or forehead rejuvenation is complete without considering rejuvenation of at least the upper eyelids, if not the entire periorbital area. When evaluating a patient’s face, I make note of the morphologic structure and anatomic features, then I evaluate the changes resulting from the aging process. *Morphology* refers to the study of the shape or form of an anatomic structure; thus it is the morphologic structure of the face, breast, and body that we change through aesthetic surgery rather than the anatomy. Yet a detailed knowledge of the anatomy of the structures themselves is essential in aesthetic surgery. This includes bony prominences, eye prominence, nasal prominence, and hairline shape, whereas aging changes include changes in the skin, subcutaneous tissues, deeper soft tissues, and even the bones.

Anatomic Features

The convexity of the forehead and any supraorbital bony prominence is noted. The thickness of the retroorbicularis oculi fat (ROOF) is assessed. The hairline and height of the forehead are noted. We also note how thick the hair is and areas where the hairline is receding.

Evaluation of the Aging Forehead and Brow

Features to Assess

Brow position—lateral and medial
Rhytids—horizontal and vertical,
at rest and on animation

Crow's-feet
Lateral orbital crowding
Skin

Evaluation should include an assessment of the position of the brow laterally and medially, the relationship of the brow to the upper eyelid, and the distance from the upper lid sulcus to the hair-bearing brow. Horizontal and vertical forehead and glabellar rhytids are assessed at rest and on animation, as are the crow's-feet. (Horizontal forehead rhytids are more common in men.) The quality, elasticity, and thickness of the forehead skin are also evaluated. Lateral orbital bunching or crowding is noted with the eyebrow at rest and when elevated.

Evaluation of Brow Position

The medial brow is usually lower than the lateral brow, with a variable arch in between. The position of the brow is judged based on the relationship of the hair-bearing brow to the supraorbital rim. A lower brow position is typically seen in men; in fact, brow position varies with sex, age, and ethnic background. The ideal brow position also varies according to fashion and culture. High-arched brows are more common and more desirable among those of Hispanic, Latin, and Mediterranean origins. Low brow position is associated with a tired, unhappy appearance, whereas excessive brow elevation is associated with a frightened or surprised look.

Low brow

Medium brow

High brow

Brow height does not necessarily signal youth. Brow fullness and shape are far more important than height, as indicated by the three images of young women shown here.

Evaluation of Rhytids, Crow's-Feet, and the Lateral Orbital Area

The patient is asked to frown, elevate the brow, and tightly close his or her eyes so that the glabella, forehead, and crow's-feet rhytids can be assessed. Brow position and the lateral orbital area are also evaluated during each of these facial movements. By observing these muscle contractions in relation to brow, eyelid, and lateral orbital movement, the surgeon can assess muscular interactions. Success in relocating the brow to the desired position will largely depend on modification of this muscle balance.

Evaluation of Skin

The quality and quantity of the skin on the forehead, upper eyelid, and lateral orbital area are evaluated for thickness, elasticity, and the presence of rhytids. The depth of the rhytids and the skin texture are noted. Any excess skin is also noted, including determining whether the skin excess is real or apparent, with particular attention to whether there is excess skin in the glabella over the nasal radix.

Treatment Options

There are a variety of surgical and nonsurgical options as primary procedures. Adjunctive treatments such as resurfacing may be performed at the same time to enhance the results. Treatment options range from toxin injections to the traditional open coronal forehead lift.

Options for Forehead Rejuvenation

The goals of forehead rejuvenation are to reposition or reshape the brow into a more youthful position or desired shape. Brow shape is far more important than brow elevation. Injection of toxins is effective not only in elevation of the brow, but also in reshaping (see Chapter 13 on toxin injections). Surgical rejuvenation of the brow leads to brow repositioning or shaping through a combination of steps, including mobilization of the brow and modification of muscles to assist in maintaining brow position and ameliorating rhytids. The open coronal lift was for years considered the standard procedure and now, with several options available, it is considered the benchmark procedure to which all others are compared. In the table below, I have compared the various procedures, including injectables, in terms of ease of exposure of the anatomic structures, muscle excision, and forehead mobilization. Scalp excision is included, because at one time it was the only option for fixation. I have found the endoscopic approach to be as effective as the coronal, and in selected patients the combination of a lateral approach with transpalpebral muscle excision has also proved satisfactory.

Options for Forehead Rejuvenation					
	Exposure	Release of Adhesions	Muscle Excision	Forehead Mobilization	Scalp Excision
Open coronal	++++	++++	+++	++++	++++
Endoscopic	++	++++	++++	++++	+
Direct approach	+++	+++	+	+++	++++
Transpalpebral	++	+	+++	+++	—
Lateral approach	+++	+++	—	+++	+++
Toxins	NA	NA	Temporary paralysis	+++	NA

Degree of effectiveness indicated by the number of pluses.
NA, Not applicable; *dash*, not possible.

Selection of a technique is based on aging changes and the patient’s anatomy. As important in this selection process is the surgeon’s familiarity and experience with each procedure, and in the final analysis, we will each select a procedure that in our hands will produce the best result with minimal morbidity.

Open coronal forehead lift

Endoscopic forehead lift

Lateral-temporal brow lift

Direct approach

Transpalpebral browpexy

Transpalpebral excision of corrugator
and procerus muscles

Toxin injection

My preferred surgical options and the frequency with which each is performed are as follows:

- Full endoscopic (20%)
- Lateral-temporal (15%)
- Transpalpebral muscle excision (5%)
- Combination—lateral-temporal plus transpalpebral muscle excision (60%)

Open Coronal Forehead Lift

The open coronal approach affords excellent exposure and facilitates release of adhesions, muscle excision, and brow mobilization. The scalp excision is tailored to elevate the brow as desired and enhance its shape. The extensive incision involved, together with the risk of sensory changes, including dysesthesias, numbness, and alopecia, are perceived as deterrents by patients who decline this approach. Since the introduction of the endoscopic approach in 1993, I have not performed an open coronal brow lift. Before 1993, only 10% to 15% of the patients undergoing facial rejuvenation in my practice would accept the open coronal lift. Today almost all of my facial rejuvenation patients undergo brow rejuvenation through one of the four procedures listed above.

There is no question that the coronal approach is the best option for some patients. These are patients in whom a high hairline and a convex frontal bone would make the endoscopic approach rather challenging. In such individuals, I prefer a combination of the lateral approach with transpalpebral muscle excision. Those with a high forehead also present a challenge to the endoscopic approach, making it technically very difficult, if not impossible. An alternative would be an open coronal biplanar approach to forehead rejuvenation, allowing shortening of the forehead height.

Endoscopic Forehead Lift

The endoscopic forehead lift is not without its limitations. Although it can be uniformly applied in every patient, the results will vary according to the patient's anatomic features as well as the aging changes present. There are certain anatomic features that make the endoscopic approach rather challenging. These patients are best served by one of the alternative approaches.

The endoscopic approach affords excellent exposure for release of the periorbital adhesions and septa; the magnification offered through the endoscope facilitates muscle excision and nerve preservation. Scalp excision is rather limited with the endoscopic approach, so elevation and maintenance of brow position rely primarily on muscle balance and fixation techniques compared with the open coronal approach, in which scalp excision maintains brow position. Even 17 years after the endoscopic approach was introduced, there is still no consensus on endoscopic fixation. Opinions range from “muscle balance is all that counts; fixation is not necessary,” to the other extreme: some insist that fixation must be permanent. I individualize the need for fixation, whether permanent, temporary, or not at all.

Endoscopic Forehead Lift: Favorable and Unfavorable Candidates

Anatomic Features	Favorable	Unfavorable
Forehead		
Height	Short	High
Convexity	Flat	Convex
Hairline		
Height	Short	High
Receding	Nonreceding	Receding
Hair quality	Thick	Thin
Skin		
Thickness	Normal	Thick
Rhytids	Superficial	Deep

Lateral-Temporal Brow Lift

The lateral-temporal approach affords excellent repositioning and elevation of the lateral brow through a temporal incision. Suturing of the temporoparietal fascia to the deep temporal fascia provides permanent fixation.

Muscle modification, although theoretically possible, especially with an endoscope, is not usually performed with this approach. This approach is best combined with a transpalpebral excision of the corrugator supercilii and division of the procerus muscles for an effective brow lift.

The best candidates for this combined approach are patients with little if any excess skin at the nasal radix, individuals requiring little if any medial brow repositioning, and those who are candidates for upper lid blepharoplasty. Advantages are the minimally invasive approach and the minimal risk of sensory changes.

Direct Approach

The direct approach is effective in elevating the lateral brow, but it is rarely performed, because it leaves a scar directly over the hair-bearing brow or in a transverse forehead line. The best candidates are elderly patients or those with pronounced lower forehead transverse creases where the scar can be concealed. This approach offers excellent brow elevation and access to the muscles. Traditionally, the excision has not been combined with muscle excision. The advantages of this method are that it is simple and quick, it can be performed with local anesthesia in many instances, and it carries minimal risk to the sensory nerves. The scar is the only potential disadvantage.

Transpalpebral Browpexy

Minimal lateral brow elevation is possible through this approach, in which the lateral brow is repositioned through the upper eyelid incision and sutured down to the periosteum. The limited elevation achieved with this approach restricts this procedure to patients with mild lateral brow ptosis without any medial brow ptosis or excess skin at the nasal radix.

Transpalpebral Excision of Corrugator and Procerus Muscles

Modification of the glabellar muscles through the upper eyelid results in improvement of glabellar lines with minimal medial elevation of the brow. Lateral brow elevation is performed through the lateral-temporal lift. The best candidates are individuals with glabellar frown lines with minimal if any medial or lateral brow ptosis. In combination with a lateral-temporal brow lift, this is my preferred choice for brow rejuvenation in patients requiring minimal or no medial brow elevation.

This patient with brow asymmetry, glabellar frown lines, and aging of the upper and lower lids underwent upper and lower lid blepharoplasty with transpalpebral excision of the corrugator and division of procerus muscles. Postoperative views and a split-face view at 18 months postoperatively show elimination of glabellar frown lines, improvement of asymmetry, and appropriate brow position.

Injection of Toxins

Toxin injections are the most popular procedure for brow rejuvenation, representing a safe and effective method for mild to moderate brow elevation through alterations to muscle balance. Advantages include the fact that it is nonsurgical and less expensive in the short run. Limitations include the temporary nature of the correction, the necessity for repeated injections, and the expense over time.

Regional Procedures

The brow lift is one component of periorbital rejuvenation. I rarely perform an isolated brow lift. In a personal series of 100 consecutive endoscopic brow lifts performed over 14 months, 79 patients underwent upper and lower lid blepharoplasty, 2 underwent upper lid blepharoplasty only, and 19 underwent lower lid blepharoplasty. Most of the patients undergoing a lower lid blepharoplasty also had a transpalpebral midface lift. There were no isolated endoscopic brow lifts during the period studied. These regional procedures reflect our approach to facial rejuvenation addressing facial zones or the entire face rather than individual components such as the brow or the eyelids.

Ancillary Procedures

The surgical procedures described reposition the brow and improve forehead and glabellar lines. Frequently, additional ancillary procedures are needed to further improve the result. These include peels and laser resurfacing, and the use of tissue fillers. We will often improve the vertical frown lines by threading a piece of autologous temporal fascia or orbicularis muscle just deep to the dermis. If the temporal fascia is exposed during the brow-lift procedure, my preference is to harvest the temporal fascia and use it as a filler. If an upper eyelid incision is made, the orbicularis oculi muscle would be an alternative source of autologous tissue. In my practice, laser resurfacing and autologous fillers for forehead and glabellar lines are the two most common ancillary procedures in forehead lifting.

This split-face view demonstrates preoperative and 5-year postoperative results after an endoscopic brow lift with external screw fixation and laser resurfacing. Other procedures performed in this patient included upper and lower lid blepharoplasties, face lift, neck lift, and perioral laser resurfacing.

CHAPTER 23

Temporal Brow Lift

FOAD NAHAI

Our goals for brow rejuvenation include repositioning the eyebrows according to cultural norms and individual tastes, eliminating or at least improving lines at rest or on animation, reducing lateral orbital crowding, and correcting excess glabellar skin over the nasal radix. Very often brow rejuvenation is combined with an upper lid blepharoplasty. In these patients the upper eyelid will be the gateway to the brow, as the lower eyelid has become an important gateway for rejuvenating the lid-cheek junction and the midface. In this chapter I will discuss the role of the upper eyelid as a gateway to the brow and its role in periorbital rejuvenation.

With the many options for brow repositioning and rejuvenation (discussed in Chapters 22, 24, and 25), selection of a procedure based on the patient's individual needs is the key. Not every patient requires, nor should every patient undergo, an endoscopic or coronal brow lift to achieve an ideal result.

Through a limited temporal incision similar to that for the three-incision endoscopic brow lift, the periorbital septa and adhesions are easily divided, and subperiosteal dissection almost to the midline is also possible. Although challenging, even glabellar muscle modification is possible through this incision. However, my preference is to modify the glabellar muscles through the upper eyelid in this combination approach. Lateral brow elevation and fixation is easily achieved with this approach.

Injectable toxins and this combination approach have reduced the number of endoscopic brow lifts in my practice. A review of the procedural statistics published annually by the American Society for Aesthetic Plastic Surgery (ASAPS) reveals that the number of brow lifts performed in the United States peaked in 2005 and currently stands below 1997 levels, when ASAPS started collecting procedural statistics.

I believe this reflects the impact of toxin use and transpalpebral muscle modification on brow rejuvenation. The lateral temporal brow lift, with or without endoscopic assistance, accomplishes the mobilization and fixation of the middle to lateral brow, whereas muscle modification is undertaken through the upper eyelid with loupe magnification.

Indications and Contraindications

The lateral brow lift is best for patients with no medial brow ptosis, no glabellar skin excess above the nasal radix, and forehead aging limited to the lateral brow. For patients with glabellar lines, modest medial brow depression, and no excess skin above the nasal radix, the combination approach, including transpalpebral modification of the glabellar muscles, is an excellent option, with results matching those achieved with endoscopic and even open coronal techniques. I often combine this approach with an upper lid blepharoplasty and midface rejuvenation or a full face lift. This is not an effective procedure for patients with significant medial brow ptosis, excess glabellar skin over the nasal radix, and deep forehead lines at rest. These individuals are better suited for an endoscopic or coronal approach.

Preoperative Planning

Brow Markings

The patient is instructed to clench the teeth while contracting the temporalis muscle, so the surgeon can palpate this; the temporal crest–temporal line of fusion is marked along the anterior border of the contracted muscle. If the sentinel vein is readily visible with the patient in a sitting position, it is marked.

Otherwise, the patient is asked to lie supine, and the sentinel vein is marked. The temporal incision is marked 2 to 3 cm behind the temporal hairline, extending no higher than the temporal crest to avoid injury to the lateral branch of the supraorbital nerve. The incision is planned directly over the muscle to facilitate anchoring of the temporoparietal fascia to the deep temporal fascia. Incisions beyond the extent of the temporalis muscle should be avoided.

Eyelid Markings

The upper eyelid is marked for blepharoplasty with the upper eyelid crease at the level of the midpupillary line, usually 8 to 10 mm above the lashes in women and a little lower in men. The lateral marking should be at least 6 mm above the lateral canthus, with a lateral extension within one of the crow's-feet, if present. At least 10 mm of skin should be preserved between the upper marking and the hair-bearing brow. In addition, I ask the patient to frown so I can mark the extent and bulk of the corrugator muscle. If there are any horizontal glabellar lines, indicating procerus hyperactivity, those are marked as a reminder to section the procerus muscles.

Operative Technique

Anesthesia

The procedure may be performed with the patient under local or general anesthesia. In my practice, because most of these procedures are combined with full facial rejuvenation, I prefer a general anesthetic. I always infiltrate the surgical field with a combination of lidocaine and epinephrine.

I prefer to do the lateral temporal brow lift first, simulate the new brow position to confirm the upper eyelid skin excision, and then proceed with the upper eyelid component of the operation.

Lateral Temporal Brow Lift

I perform this portion of the operation exactly as I do for an endoscopic brow lift. The incision is placed coronally or horizontally or anywhere in between, depending on the desired final brow position. The incision is made and continued through the temporoparietal fascia onto the deep temporal fascia. The initial dissection is made bluntly, with the scissors pushing along the deep temporal fascia toward the lateral orbital rim to establish an optical cavity. From this point on, the dissection can continue under endoscopic control or, my preference, direct vision with the aid of a lighted retractor or an Aufricht retractor and a headlight.

The endoscope is introduced, and dissection proceeds rapidly with an endoscopic dissector in this avascular plane toward the lateral orbital rim. The sentinel vein is easily identified, and I prefer to preserve it. The septa and adhesions are released, usually with the endoscopic dissector. To ensure complete release and thus mobilization of the lateral brow, I make a point of skeletonizing the sentinel vein.

Some of the septa and adhesions, especially beyond the vein, may require division with endoscopic scissors. Following the skeletonizing of the sentinel vein, dissection continues minimally beyond the orbital rim and then laterally through the temporal crest and into the subperiosteal space.

The extent of the medial subperiosteal dissection varies from patient to patient and depends on brow shape and the desired final result.

At this stage the lateral brow is tested with upward traction at the skin edge to ensure mobility by observing the upward and medial rotation of the lateral brow. If the lateral brow moves only minimally, further dissection must be performed; otherwise, there may be no brow elevation. The brow is not fixed at this stage. I then proceed with upper lid blepharoplasty and glabellar muscle modification.

Transpalpebral Glabellar Muscle Modification

I perform the glabellar muscle modification with loupe magnification. The upper eyelid skin–muscle is excised as marked. The dissection proceeds superiorly deep to the orbicularis oculi, facilitated by two Blair retractors suspending the upper edge of the resected orbicularis. I prefer to operate with the cutting current of the Colorado tip needle. Alternatively, the dissection can be performed easily with a pair of scissors. At this stage, even if I am planning to resect upper eyelid fat, I leave the orbital septum intact, and any planned fat removal is delayed until after the glabellar muscle is excised, thus facilitating dissection of the orbicularis off the orbital septum. Laterally, the dissection is continued along the deep surface of the orbicularis until the lateral orbital dissection through the eyelid is continuous with the endoscopic dissection from above.

Once the communication between the eyelid and brow plane of dissection has been established, I make a number of radial cuts into the lateral orbicularis, not to permanently weaken it but to weaken it temporarily to prevent the downward pull of the orbicularis during the early postoperative phase to help maintain lateral brow position. The radial cuts are made in the muscle with the Colorado tip, and with a finger placed behind the hair-bearing brow pushing the muscle forward to facilitate scoring.

Medially, the dissection approaches the supraorbital rim. The orbicularis fibers running horizontally must be divided to reach the diagonally running muscle fibers of the corrugator supercilii muscle.

Branches of the supratrochlear nerve may also be visible at this stage.

The orbicularis muscle is divided with the Colorado tip or by spreading with the tips of scissors or a fine mosquito clamp. This immediately brings the corrugator muscle and a branch or two of the supratrochlear nerve into view.

Although the corrugator muscle can be divided in stages, I prefer to insert the tips of the fine mosquito clamp around the entire muscle belly if possible; otherwise, I insert the tips partially through it, spread the tips, and resect the intervening segment of muscle. I often encounter a branch or two of the supratrochlear nerve coursing through the muscle. *The supraorbital nerve is usually lateral to this dissection.*

A segment of the muscle has been removed, revealing at least two intact branches of the supratrochlear nerve. These nerves are often accompanied by blood vessels that can bleed. I make every attempt to avoid these vessels. If they bleed, I cauterize them with a bipolar cautery rather than a unipolar coagulating current. The muscle division/excision should be complete to prevent postoperative recurrence of glabellar function and lines. At the completion of the procedure, there should be a significant gap in the muscle with preservation of the supratrochlear and supraorbital branches. Theoretically, dissection in the upper medial corner of the orbit may injure the trochlear or superior oblique muscles. Such injuries are very rare and are easily avoided by limiting the dissection behind the origin of the corrugator muscle.

It is rare that any contour deformities result from this excision of the corrugator; however, if there is any concern, fascia or periorbital fat serve well as filler between the cut ends of the corrugator muscle.

In patients who have transverse glabellar or dorsal nasal skin lines resulting from procerus muscle activity, the procerus is transversely divided through the blepharoplasty incision by elevating the orbicularis and then pushing a pair of scissors deep to the skin toward the nasal radix, cutting the fibers off the procerus under the skin. If necessary, periorbital fat is excised at this time.

The next step is brow fixation. The brow is rotated upward and medially, and the temporoparietal fascia is anchored down to the deep temporal fascia. I usually place two sutures of 2-0 PDS between the temporoparietal fascia and the deep temporal fascia in a diagonal or vertical vector. More medial screw fixation may be necessary, but this is rare. A minimal amount of excess scalp is excised, and the scalp incision is closed with staples. The upper eyelid incision is closed.

Postoperative Care

To minimize swelling, the patient's head is kept elevated, and ice packs are applied to the periorbital area.

Results

This middle-aged woman underwent a temporal brow lift, transpalpebral corrugator excision, a nasal compartment orbital fat flap to correct the A-frame deformity of the upper lids, transconjunctival lower blepharoplasty with fat distribution, and a face lift. She is shown several months postoperatively.

This 50-year-old woman exhibited aging of the upper and lower lids, lid-cheek junction, and face. Rejuvenation of the periorbital area and lower face was planned. She underwent a lateral temporal lift, upper and lower blepharoplasty, and a short-scar blepharoplasty. She is shown 4 years postoperatively; the improved lateral brow position has been maintained.

Problems and Complications

Infection and bleeding are rare. Alopecia may be seen along the temporal incision line. This risk is minimized by avoiding excessive tension in the scalp closure and limiting the use of coagulating current along the cut edges of the incision. Inade-

quate lateral temporal release may lead to relapse or recurrence of brow ptosis. The upper eyelid procedure increases the risk of bleeding and swelling beyond that of a standard upper eyelid blepharoplasty. Hemostasis in the corrugator muscle bed is essential. Unless combined with lower lid procedures, chemosis and other blepharoplasty complications are rarely seen.

Concluding Thoughts

Combining a lateral/temporal lift with an upper lid blepharoplasty and transpalpebral excision of the corrugator muscle through the upper eyelid is a safe and effective option for rejuvenation of the brow. It requires no special equipment beyond a pair of loupes. The best candidates have moderate lateral brow ptosis, appropriate medial brow position, and moderate vertical glabellar frown lines.

Clinical Caveats

The temporal incision must be kept over the temporalis muscle. This not only eliminates the risk of injury to the lateral branch of the supraorbital nerve, it also ensures that the temporo-parietal fascia can be anchored down to the deep temporal fascia.

Complete release of the lateral orbital attachments, adhesions, and septa is essential; otherwise, the lateral brow cannot be successfully elevated.

Dissecting instruments should be kept firmly down over the deep temporal fascia to avoid frontal branch injury.

Vertical spreading in the vicinity of the sentinel vein should be avoided to minimize the risk of stretch injuries to the frontal branch.

Loupe magnification greatly facilitates the transpalpebral excision of the corrugator muscle.

Connecting the lateral upper lid and brow dissections through the lower lid dissection facilitates lateral brow elevation.

Serial scoring of the lateral orbicularis oculi muscle minimizes downward pull of the orbicularis during the postoperative period, which assists fixation of the lateral brow position.

CHAPTER 24

Endoscopic Brow Lift: *The Three-Portal Approach*

FOAD NAHAI

Low brow

High brow

Full brow

Deflated brow

For too long we have focused on brow position rather than brow shape and fullness as representing beauty and youth. Perhaps our emphasis on brow height during the early days of endoscopic brow lifting was not only a carryover of the thinking in the early 1990s, but also a desire to establish that endoscopic brow lifting could elevate and maintain brow height. Since then, our understanding of facial aging and the role of volume and deflation has been advanced significantly through the work of Lambros and Coleman. Numerous publications have also established the efficacy of the endoscopic brow lift to elevate and maintain brow position. Our current view is that a youthful or beautiful brow is related more to volume and shape than to height.

Endoscopic procedures have been modified with these ideals in mind. Repositioning the brow with amelioration of forehead and glabellar lines is an integral part of periorbital and full facial rejuvenation. In a balanced, youthful face, the eyebrow is lower medially and higher laterally, with a variable arch in between. Several publications have attempted to describe the youthful or beautiful brow through numeric measurements and formulas. However, there are many youthful and beautiful women without high eyebrows. Given these variations of beauty and normalcy, neither aging nor the success of rejuvenation in the periorbital area should be judged by brow height; brow shape and volume are far more important than brow height.

Early signs of brow and periorbital aging include deflation and brow ptosis with a lowering of the medial and lateral hair-bearing brow and development of vertical glabellar and horizontal forehead lines. These changes often result in alterations to facial expression, producing a tired, concerned, or even angry look. There is also real or apparent excess skin on the upper eyelid. A variety of techniques are available to reposition and reshape the brow and to soften vertical and horizontal frown lines. Most involve mobilization, repositioning, and fixation of the forehead and brow with modification of the forehead musculature. The open standard coronal brow lift was for many years the only option for forehead rejuvenation; it remains an effective, proven operation, the benchmark against which other techniques are measured.

In 1992 Isse and Vasconez independently pioneered what we refer to today as the *endoscopic brow lift*. Since that time, this technique has evolved significantly: it has been simplified, the instrumentation minimized, and the anatomy defined. It has steadily gained in popularity and was once, without doubt, the most common endoscopic procedure, not only in aesthetic surgery but in all of plastic surgery. However, the popularity and effectiveness of toxins in reshaping and repositioning the brow and the effectiveness of transpalpebral glabellar muscle modification combined with a temporal brow lift have affected the number of endoscopic brow lifts performed. Despite these recent developments, the procedure continues to enjoy tremendous patient acceptance. Before endoscopic forehead lifts were introduced, approximately 1 in 10 of my patients undergoing a face lift would accept a coronal brow lift. Today some form of brow lift, whether endoscopic, transpalpebral, or lateral temporal, is my routine for almost all patients undergoing facial rejuvenation.

My experience with several hundred endoscopic brow lifts over 16-plus years has been favorable. Patient acceptance has been high, morbidity low, and my results have compared favorably with those of the coronal brow lift.

The endoscopic approach affords excellent exposure for release of periorbital adhesions; muscle excision and nerve preservation are facilitated through the endoscope's magnification. The approach results in shorter scars and reduces the risks of sensory denervation of the scalp and alopecia. However, scalp excision is limited with this approach, so that elevation and maintenance of brow position must rely on muscle balance and fixation techniques, compared with the open coronal method in which scalp excision maintains brow position.

Advantages and Disadvantages of the Endoscopic Brow Lift

Advantages

- Excellent exposure for release of periorbital adhesions
- Shorter scars
- Endoscopic magnification
- Reduced risk of alopecia and scalp sensory changes

Disadvantages

- Initial cost of equipment and special instrumentation
- Technology-dependent nature of the procedures—equipment failure may prevent completion of the procedure
- Learning curve involved
- Need for additional fixation

Indications and Contraindications

GOOD CANDIDATE

POOR CANDIDATE

The best candidates for an endoscopic forehead lift are patients with short, flat foreheads with nonreceding, thick hairlines and normal skin, moderate rhytids, and minimal true skin excess laterally and over the nasal radix. Poor candidates have a high convex forehead, a high, receding hairline with thin hair, thick skin, deep rhytids, and true excess skin on the forehead and brow.

Forehead height and shape are limiting factors for a rigid endoscope. In a patient with a short, flat forehead, it is relatively easy for the surgeon to maneuver the endoscope to visualize the glabellar musculature and orbital rim. A convex forehead makes it difficult to maneuver the rigid, straight endoscope, and a high forehead places limitations on the reach of the endoscope.

Pertinent Anatomy

Key anatomic points include the sentinel vein, the temporalis muscle and temporal crest, periorbital septa and adhesions, glabellar muscles, and the supratrochlear and supraorbital nerves.

Sentinel Vein

De La Plaza et al described and named perforating vessels in the temporal region sentinel vessels of the lateral wall of the orbit. These zygomaticotemporal veins are communicating veins between the superficial and deep systems. There are usually two veins, one medial and the other lateral; the medial is larger and is referred to as the *sentinel vein*.

This endoscopic view shows the medial and lateral zygomaticotemporal veins. The smaller, or lateral one, is often accompanied by the zygomaticotemporal nerve.

The sentinel vein (*top*) is a useful landmark for preoperative planning (*bottom*) and a key point for the release of the periorbital septa and adhesions during the operation. In most patients in the recumbent position, the sentinel vein is located 1.5 cm above and lateral to the lateral canthus. The lowest of the frontal nerve branches usually passes approximately 1 cm above the level of the sentinel vein. Thus the sentinel vein defines a danger zone for the frontal branch. I can operate rapidly toward the zone with safety; however, when approaching the vein, the dissection is slowed under endoscopic control to prevent any direct damage or stretching of the nerve.

Temporalis Muscle and Temporal Crest

The temporal crest marks the transition from the dissection to the temporo-parietal fascial (subfascial) to the subperiosteal plane by elevating the temporal line of fusion at the temporal crest. The temporal crest also marks the lateralmost course of the lateral branch of the supraorbital nerve. Preoperatively I ask patients to clench their teeth, and I mark the temporal crest, as seen here. My left hand rests over the contracting muscle while the pen held in my right hand outlines the temporal crest just anterior to the contracting muscle. The sentinel vein is also marked.

Periorbital Septa and Adhesions

Although several authors have referred to ligaments in the periorbital area, Moss et al pointed out that rather than true ligaments, there are multiple septa and adhesions in the periorbital area. To mobilize the brow, especially the lateral periorbital brow, all of the septa and adhesions must be completely divided. I have found that skeletonizing the sentinel vein effectively releases septa and adhesions, allowing elevation of the brow.

Glabellar Muscles

The corrugator supercilii is the first muscle encountered with the endoscopic approach in the glabellar region. Medial to the corrugator are fibers of the orbicularis oculi muscle, called the *depressor supercilii*. More superficially and in the midline lie the procerus muscles. The supratrochlear nerves run within or just superficial to the corrugator. The bulk of the orbicularis muscle lies superficial to the corrugator and is only viewed once the corrugator has been excised.

Supratrochlear and Supraorbital Nerves

The supratrochlear nerves are several small filamentous nerves lying within or just superficial to the depressor supercilii and corrugator muscles. These nerves almost always emerge through notches in the supraorbital rim. Injury to one or more of these small filaments is inevitable during excision of the corrugator muscle and is of relatively little significance. A useful clinical landmark for the supratrochlear nerves is the vertical glabellar frown line if present; it is usually 1.5 to 2 cm from the midline.

The supraorbital nerve is much larger than the supratrochlear nerves; it is usually one single large nerve, although occasionally two or three branches may be seen. It emerges from the orbit through a definite notch or occasionally through a foramen that may be up to 2 to 4 cm above the supraorbital rim. Although the supratrochlear nerves lie within the fibers of the corrugator, the supraorbital nerve is usually deep to the corrugator. The lateral branch of the supraorbital nerve may course as far lateral as the temporal line of fusion. Any incision in the scalp that is medial to the temporal line of fusion runs the risk of dividing this branch, resulting in sensory loss in the forehead. A useful landmark for this nerve is the midpupillary line, or a distance of 3 to 4 cm from the midline.

Preoperative Assessment

Patient evaluation includes an assessment of the medial and lateral brow position, position of the brow in relation to the upper eyelid, assessment of glabella and forehead lines at rest and on animation, and assessment of frontal bone convexity, forehead height, and hairline. This evaluation influences the surgeon's choice of procedure. If the endoscopic brow lift is chosen, this evaluation influences the location of the incisions, extent of muscle modification, and fixation techniques, if any are needed.

In patients with normal or minimal medial brow descent, minimal or no glabellar skin excess over the radix, modest lateral brow ptosis, and superficial forehead lines at rest, I prefer the combination of a lateral temporal brow lift and transpalpebral corrugator excision, as described in Chapter 25.

The surgeon advises the patient about the following:

- The number, location, and length of the incisions, and if fixation is required, the type of fixation (for example, external screws or an Endotine fixation device [Coapt Systems, Palo Alto, CA]) and any additional incisions required for fixation

- Although the risk is minimal, there may be some alopecia at the incision sites and around the external screw fixation sites

- Temporary or even permanent sensory changes may occur in the scalp

- Some downward movement of the brow will occur within the first few months after the procedure, and over the long term the brow will not be as high as the initial result

Preoperative Planning

As with any technology-dependent technique, the surgeon must have a basic understanding of the principles. In endoscopic aesthetic surgery, the surgeon needs to have the following:

- The necessary training
- Appropriate mechanical equipment
- Knowledge of equipment troubleshooting and safety measures
- The technical skills to perform the procedure

Today endoscopic equipment, including the endoscope, camera, monitors, and so on, has become standard in operating rooms where aesthetic surgery is performed. Operating room personnel are now quite familiar with this equipment and its maintenance.

Team Preparation

The Surgeon

- Take a CME-approved endoscopic plastic surgery teaching course.
- Familiarize yourself with the endoscope and camera.
- Study a DVD or videotape of the procedure.
- Watch a colleague perform the procedure.
- If possible, have an experienced endoscopic surgeon assist you with your first case.
- Practice setting up the equipment.

The Operating Room Staff

- Receive in-service instruction from experienced operating room personnel or a manufacturer's representative.
- Dismantle and set up equipment.
- Learn troubleshooting techniques.
- Be aware of the location of backup equipment.
- Stage a dress rehearsal before performing an actual procedure.
- Learn the names of the endoscopic instruments.
- Arrange endoscopic instruments in the order in which the surgeon will use them.
- Watch a DVD or videotape of a procedure.
- Visit an operating room where these procedures are routinely performed.

Minimum Equipment Needs

Endoscope	Endoscope warmer
4 or 5 mm 30-degree angle Hopkins rod	Defogging solution
Endoscopic cannula or endoretractor—	Electrocautery
4 or 5 mm	Instrumentation
Endoscopic cart	Curved elevators (two or three)
Monitor	Endoscopic scissors
Light source	Insulated graspers
Camera (at least three-chip)	Fixation devices

Originally, up to 25 special instruments were designed and marketed for the endoscopic brow lift. Today most of us have our own half-dozen or more favorite instruments for this procedure.

As a safeguard, it is important to have a backup system available, including a second endoscope, camera, and light source. These are readily available in a large hospital or surgical center but perhaps not in a small office-based operating room. Before every operation, either the surgeon or the operating room nurse should not only test the system but also inspect all of the instruments, especially the endoscopic graspers. I specifically look for breaks in the insulation of the graspers. Because we use the graspers for cauterization, any break in the insulation could cause a burn.

Markings

The major landmarks for this procedure include the sentinel vein, the temporal crest, and fixation vectors. If the sentinel vein is readily visible with the patient sitting down, I put a mark over it and then draw the likely course of the frontal branch of the facial nerve 1 cm or so above the sentinel vein. If the sentinel vein is not visible with the patient in the sitting position, I ask the patient to lie flat, and in most patients the vein is then visible.

I then ask the patient to clench his or her teeth firmly. This enables me to palpate the muscle with my left hand as my right hand outlines the temporalis muscle and the temporal crest on the forehead just anterior to the contracting muscle. I then mark the access incision 1 or 2 cm behind the temporal hairline, making certain that I am over the temporalis muscle. This will facilitate fixation of the temporo-parietal fascia down to the deep temporal fascia.

These markings are made symmetrically on both sides of the head. The orientation of this temporal incision varies from radial to coronal. I individualize this based on the patient's anatomy and our goals. I prefer a coronal or horizontal incision to a radial incision, because with the radial incision I am limited to one fixation suture, whereas the other approach allows me to put in a minimum of two fixation sutures.

I then ask the patient to frown, which outlines the origin and insertion of the corrugator muscle. Next I mark the glabellar frown line and the course of the muscle lateral to it to be a guide for muscle excision. I also mark the midpupillary line, indicating the course of the supraorbital nerve. Another mark is placed 2 to 4 cm above the orbital rim in the midpupillary line, indicating a danger zone where the supraorbital nerve could emerge through a foramen.

Finally, the vectors for fixation are marked. For temporal fixation, I routinely rely on vector from the alar base to the lateral canthus projected onto the forehead. An alternative line is drawn from the oral commissure to the lateral canthus and then onto the forehead. This vector provides a more vertical and upward elevation of the lateral brow.

If extra fixation is planned, such as with a screw or an Endotine device, I individualize these vectors. In general, I place them on the scalp in line with the most convex arch of the brow.

The projection of the most convex part of the brow onto the scalp is marked as the site for additional fixation.

The patient is shown with all of the final markings.

Patient Positioning

The patient is placed supine on the operating table with the head extending slightly beyond the headpiece. This facilitates maneuvering of the endoscope and endoscopic instruments. The procedure can be performed with the patient under local or general anesthesia. I prefer a general anesthetic because, in my practice, endoscopic brow-lift procedures are almost always performed in combination with other periorbital and facial rejuvenation procedures.

Operative Sequence

1. Hair preparation
2. Infiltration
3. Right temporal incision and dissection
4. Left temporal incision and dissection
5. Central access incision
6. Subperiosteal dissection
7. Division of periosteum from one lateral orbital rim to the other
8. Muscle modification
9. Drain placement
10. Closure of central access incision
11. Placement of temporal fixation sutures
12. Additional fixation, if needed
13. Tying of temporal fixation sutures
14. Temporal scalp excision, if needed

Operative Technique

Hair Preparation

With the patient under general anesthesia, I cleanse the hair with a soapy solution and braid the hair to expose the proposed incision sites. Braiding keeps the hair out of the way during the procedure; alternatively, the hair may be stapled on each side of the proposed incisions.

Infiltration

The brow area is infiltrated with a solution of 1% lidocaine (Xylocaine) and epinephrine 1:100,000, encompassing the entire area that will be undermined.

Temporal Incisions and Dissection

I begin the procedure on the right side; the incision is made through the scalp down to the deep temporal fascia over the temporalis muscle.

With a hook elevating the lower edge, I dissect in the plane between the temporoparietal fascia and the deep temporal fascia. This is a bloodless field, and the dissection proceeds rapidly toward the lateral orbital rim.

Once the dissection is started, I switch from Metzenbaum scissors to a Ramirez No. 4 dissector. I dissect rapidly toward the orbital rim, without the endoscope but under direct vision, with an Aufricht retractor and a headlight, keeping the tip of the dissector firmly down on the deep temporal fascia. This avoids any possible risk of damage or stretching of the frontal branch. The dissection is stopped within 1 cm of the sentinel vein. This nonendoscopic dissection is continued medially through the temporal line of fusion and then in a superior direction so that the temporal line of fusion is elevated and the subperiosteal space is entered. At this stage the endoscope is introduced, and with the same dissector the dissection is continued toward the sentinel vein and the lateral orbital rim.

The sentinel veins are easily identified. In most patients I am able to divide the septa and adhesions around the sentinel vein and extend the dissector into the upper eyelid, deep to the orbicularis and the retroorbicularis oculi fat (ROOF).

If the adhesions around the sentinel vein cannot be taken down with the dissector, I complete their division with the endoscopic scissors under direct endoscopic control.

I make every effort to preserve and skeletonize the sentinel vein. At this stage I place traction on the lower edge of the incision, pulling the brow upward. This confirms whether all of the adhesions have been released and that the lateral brow is now mobile. Failing to release the lateral brow limits the result. The procedure is then repeated in exactly the same way on the left side.

Central Access Incision

The central access incision is made in the midline, approximately 1 cm behind the hairline. This is a radial incision extending straight through to the periosteum.

The subperiosteal dissection is initiated with a straight periosteal elevator and extended toward the glabella, laterally toward the temporal incisions, and posteriorly for 3 or 4 cm. This dissection is fairly rapid, and I progress through two other periosteal elevators with increasing curvature.

The subperiosteal dissection is connected with both temporal dissections and extended in the midline to the glabella and to a level approximately 2 to 4 cm above the supraorbital rim. This subperiosteal dissection is performed blindly.

The endoscope is then introduced through this central access incision so that the subperiosteal dissection, which is completed down to the supraorbital rim, is continued under endoscopic control to permit identification and easy preservation of the supraorbital nerve if it emerges through a foramen above the supraorbital rim.

Division of the Periosteum

At this stage the periosteum is divided from one lateral orbital rim to the next. This periosteal division serves two purposes:

1. Division of the periosteum to allow further brow elevation laterally. The medial brow and glabellar periosteum may be left intact if medial brow elevation or separation is not desired.
2. Division of the periosteum to permit access to the glabellar musculature.

Muscle Modification

After the periosteum is divided, the corrugator, procerus, and depressor supercillii are easily seen. The direction of the muscle fibers aids in identifying each individual muscle. The procerus fibers have a slightly deeper color, with the fibers running vertically. The depressor fibers are lighter in color and vertically oriented also, whereas the corrugator fibers run diagonally.

I have tried various instruments for muscle modification, including Takahashi forceps, coagulating current, a laser, and even a periosteal elevator. My preference now is the endoscopic grasper; I grasp a little muscle at a time and tease it upward.

I have found that the muscle tears very easily, but the branches of the supratrochlear nerve are more resilient. Depending on the bulk of the muscle and the severity of the patient's glabellar lines, I vary the extent of muscle division and the amount of muscle I remove.

At the end of the muscle modification, the branches of the supratrochlear nerve should lay bare within the optical field. Sometimes with a heavy muscle I extend the dissection laterally, superficial to the supraorbital nerve.

The supraorbital nerve and a separate lateral branch are shown after muscle excision. I rarely need to cauterize any vessels. The combination of the head of the table being slightly elevated and epinephrine infiltration yields a relatively bloodless field. Occasionally bleeding is encountered from veins accompanying the supratrochlear and supraorbital nerves; this bleeding is easily controlled by holding the vein with the endoscopic grasper, pulling it away from the skin, and then gently cauterizing it. It is important to pull the vein away from the skin and to set the electrocautery on a low level to avoid injury to the surrounding nerves and even the overlying skin. If there is bleeding in the field, I have found Neuro Patties to be very useful for drying up the field. I also like to have a 10 ml syringe filled with saline solution attached to the endoscopic sheath for irrigation. This irrigation is useful for clearing the field, if needed, but most of all to eliminate fogging of the endoscope.

Drain Placement

I routinely drain all endoscopic brow lifts for up to 24 hours. Although there is minimal drainage, 20 to 25 ml at most, I believe this makes a big difference with regard to upper lid swelling and ecchymosis, especially when the endoscopic brow procedure is combined with upper lid blepharoplasty. I prefer to place a 10 Fr drain directly along the supraorbital rim with the tubing exteriorized behind the ear on one side.

Closure

The central access incision is closed first. I routinely fix the brow in the temporal area with one or two sutures of 2-0 PDS, anchoring the temporoparietal fascia down to the deep temporal fascia. If additional paramedian fixation is needed (between the temporal crest and the central access incision), I place temporal fixation sutures, but I do not tie them until the paramedian fixation is performed. Currently my choices for paramedian fixation include external screw fixation or an absorbable Endotine device. An Endotine device affords permanent fixation and multidirectional vectors. It does require a separate incision and a special drill bit. Whether it is an Endotine device or an external screw, a single hook is placed on the scalp behind the planned fixation site. The scalp is then lifted, pulled upward, and rotated medially.

A hand drill and screw holder are shown. The drill has a 5 mm stop. For external screw fixation, with the assistant maintaining the brow in the desired position through the hook, a stab incision is made in the scalp, and a drill hole is made with the hand drill. A self-tapping screw, 16 mm in length with a 5 mm thread, is placed in the drill hole and secured. A staple is placed behind this screw, maintaining the brow position.

A separate 2 cm incision is made according to the preoperative vectors for insertion of the Endotine device (*right*). The brow is then pulled close to its desired position. The Endotine device has five prongs or tines to engage the periosteum and hold it in the new position.

Next, with a power drill, a drill hole is made into which the device is placed with the tines pointing backward. The Endotine device is inset into the drill hole. The device may be rotated according to the fixation desired.

The scalp is pulled upward and rotated medially. Then the scalp is pushed down onto the device to engage the tines.

Once this paramedian fixation has been completed, the temporal fixation sutures are tied, minimal scalp excision in the temporal area is performed if needed, and the temporal incisions are closed.

Fixation Choices

Currently there is no consensus among surgeons regarding the preferred method of brow fixation. In fact, there is even some debate about whether any fixation is needed, because the muscle balance between the glabella and the frontalis is altered, and therefore brow position will likely be maintained.

Who needs fixation, and which methods work? Temporal fixation—anchoring of temporoparietal fascia down to the deep temporal fascia—is universally applied to every patient in my practice. Paramedian fixation between the temporal crest and midline with an upward and medial rotation is selectively applied on the basis of the patient's aging changes, brow position, brow shape, sex, and desired results.

I am more likely to use permanent paramedian fixation in a man with heavy forehead skin and significant brow ptosis than in a woman with moderate or minimal brow ptosis and normal forehead skin.

Endoscopic Brow Fixation Methods

Temporary

Emory tapes
Bolster sutures
Fibrin glue
External screws

Permanent

Vertex sutures
Internal screws
Permanent
Absorbable
Mitek anchors
Permanent
Absorbable
Cortical tunnels
Endotine device

A variety of methods for brow fixation are available. I have had experience with all of the fixation methods listed here, except for the Mitek anchors. The fixation methods can be further divided into temporary and permanent fixation. How long does it take for brow position to become fixed? How long does the periosteum take to adhere? Opinions vary: from 8 days to as long as 6 weeks. The only study available in a rabbit model showed that it took the periosteum 6 weeks to stick back down. The general consensus is that to be effective, the fixation should last at least a couple of weeks. Based on this information, I consider the external screws, which we normally take out at 1 week to 10 days, to be temporary and the Endotine device to be permanent.

Ancillary Procedures

Frequently ancillary procedures are performed in combination with an endoscopic brow lift to further improve the result. These include peels, laser resurfacing, and injection of tissue fillers. In patients with deep vertical frown lines at rest in whom muscle modification alone will not eradicate the lines, I thread a piece of autologous tissue, temporal fascia, or orbicularis muscle just deep to the dermis. I have found this method to be rapid, effective, and relatively free of problems or complications. The volume of the transferred tissue is preserved over time.

This woman in her thirties had brow ptosis and very deep, established glabellar frown lines. She was a candidate for endoscopic brow lift and autologous temporal fascia grafts to the grade 5 rhytids in her glabellar area.

During the endoscopic brow lift for this patient, a 1 by 3 cm piece of deep temporal fascia was harvested. The fascia was split in half longitudinally into equal 0.5 by 3 cm strips.

With a No. 57 Beaver blade, a subdermal tunnel was made under the left glabellar rhytid. The blade not only creates the tunnel but also releases the deep dermal attachments. The blade exits the lower end of the rhytid, making a small incision in the skin.

A fine grasper is passed through the tunnel from above and out through the lower incision. The grasper firmly holds the fascial strip, which is pulled into the tunnel. The procedure is repeated on the right side. With both strips placed subdermally, the protruding fascia is trimmed flush with the skin and the stab incisions are closed with 6-0 suture material. My preference is 6-0 rapid-absorbing catgut.

Comparing the preoperative view with the patient's postoperative results 1 year after treatment demonstrates improved brow position, improved upper eyelids without an upper eyelid blepharoplasty, and effective elimination of the glabellar frown lines. The split-face image confirms the improvement.

Postoperative Care

Because most endoscopic brow procedures in my practice are performed in conjunction with other aesthetic facial procedures, these patients usually spend the night in our overnight facility. They are kept comfortable, with the head elevated and an ice pack over the eyes. Every effort is made to alleviate nausea and to monitor blood pressure and keep it under control.

Antihypertensive medication and sedatives are administered routinely in men and as needed in women. The drain is usually removed the next morning before the patient goes home. The patient is advised to keep his or her head elevated, to avoid strenuous activity for up to 3 weeks, and is scheduled to return for follow-up within 3 to 6 days.

Outcomes

Patient acceptance of this procedure has been high. There have been few problems such as alopecia, dysesthesias, and temporary nerve paralysis. In a personal series of approximately 700 patients, there was no permanent facial nerve paralysis. Temporary facial nerve paralysis was seen in less than 1% of patients, and alopecia at the screw fixation site was seen in 4%.

This woman's preoperative view demonstrates brow asymmetry, brow ptosis, glabellar and transverse forehead rhytids (grade 4), and aging of the upper and lower eyelids with crow's-feet. The patient underwent an endoscopic brow lift with external screw fixation and upper and lower lid blepharoplasty. The early postoperative view and a split-face image demonstrate improvement of brow asymmetry, elevation of the brow position, and improvement of rhytids.

A close-up of the left side of her scalp shows a 1 by 1.5 cm area of alopecia at the site of the external screw fixation. This area was excised to eliminate the bald spot.

Most patients experienced mild temporary dysesthesias. I have personally reoperated on only one of my earliest endoscopic brow patients for recurrent brow ptosis.

Results

This woman in her late forties had brow ptosis, grade 5 glabellar lines, and full facial aging; she underwent an endoscopic brow lift with no paracentral fixation. She also had upper and lower eyelid blepharoplasty and face and neck lift. Her postoperative result at 18 months demonstrates an elevated brow position with significant improvement in the glabellar lines. This is most readily apparent in the split-face image, demonstrating elevation of the medial and lateral brow.

This woman in her early fifties had heavy, ptotic brows with grade 4 glabellar rhytids. She underwent an endoscopic brow lift with external screw fixation as well as a lower lid blepharoplasty and transpalpebral midface lift. Her postoperative result demonstrates improvement of brow position, amelioration of rhytids, and improvement of the lower lid-cheek junction and midface area.

Preoperative

4 months postoperatively

7 years postoperatively

Preoperative

7 years postoperatively

This man in his forties had a heavy ptotic brow and deep grade 5 transverse forehead lines. He underwent an endoscopic brow lift with Emory taping, upper lid blepharoplasty, and transconjunctival removal of fat from the lower eyelids. Postoperative results at 4 months and at 7 years demonstrate maintenance of brow elevation, including the exaggerated medial brow elevation that was typical of our early endoscopic brow lifts with the central Emory T to V scalp excision. I abandoned the central scalp excision because it led to these exaggerated medial brow elevations.

Preoperative

7 years postoperatively

8 years postoperatively

Preoperative

8 years postoperatively

Preoperative

8 years
postoperatively

This woman in her late forties had heavy brows and brow ptosis. She had an endoscopic brow lift with Emory taping. She is shown at 7 years and at 8 years postoperatively, demonstrating maintenance of the elevated brow position.

This 40-year-old woman had brow ptosis, grade 4 glabellar lines, and aging of the midface and neck. Despite the high forehead, she elected to have an endoscopic brow lift, a lower lid blepharoplasty with transpalpebral midface lift, and an endoscopic neck lift. The postoperative view demonstrates repositioning of the brow, amelioration of the glabellar lines, improvement of the upper eyelids (without an upper eyelid blepharoplasty), and improvement of the lower lid and midface area.

Concluding Thoughts

Although the use of neurotoxins and even less-invasive brow lift techniques (see Chapter 23) have gained in popularity and the overall numbers of coronal and endoscopic brow lifts are in decline, there is still a role for the endoscopic approach. Based on my 16-plus years of experience, during which I have performed several hundred endoscopic brow lifts, I conclude that the procedure is effective and safe, with lasting results. With technical modifications, the exaggerated medial brow elevation has been eliminated. The need for fixation, if any, and the type of fixation remain a matter of debate, and we each have our own thoughts based on experience.

Clinical Caveats

An endoscopic brow lift is a technology-dependent procedure. The surgeon and operating room personnel should be familiar with the endoscopic equipment and be able to troubleshoot problems involving the camera, light source, and monitor. The success of this procedure depends on adequate release of the periorbital septa and adhesions.

Vertical spreading should be avoided during the temporal dissection to prevent stretch injury of the frontal branch of the facial nerve.

Keeping the dissector firmly down on the deep temporal fascia and temporalis muscle prevents any injury to the frontal branch of the facial nerve.

Release of the periosteum is essential for brow elevation.

While resecting the glabellar musculature, the surgeon should avoid removal of subcutaneous fat, which could result in a depression.

Every attempt should be made to preserve the sentinel vein. Sacrifice of the vein leads to engorgement of the superficial veins, which will become readily visible in thin-skinned individuals.

If medial brow elevation is not desired, subperiosteal dissection should be avoided in the medial brow area.

CHAPTER 25

Other Approaches to Brow Lift

FOAD NAHAI

A variety of options are available for rejuvenation/repositioning of the brow and forehead, ranging from the open coronal forehead lift to neurotoxins and including the following:

- Coronal brow lift
- Endoscopic forehead lift
- Lateral-temporal brow lift
- Transpalpebral excision of corrugator and procerus muscles
- Lateral-temporal brow lift combined with transpalpebral excision of corrugator and procerus muscles
- Direct brow lift
- Transpalpebral browpexy
- Injection of neurotoxins

Successful rejuvenation of the brow and forehead includes repositioning of the hair-bearing brow, improvement of vertical glabellar and horizontal forehead lines, reversal of the brow descent, and conversion of a tired or angry expression into a rested and contented look.

As surgeons we look for safe and efficacious procedures rendering lasting results, whereas our patients look for an effective procedure with minimal scarring and a short recovery time.

The coronal lift remains the benchmark against which the results, morbidity, and longevity of the other procedures can be compared. Not everyone undergoing facial rejuvenation is a candidate for or will consent to a coronal brow lift. Therefore alternatives must be sought to provide the desired result without the coronal incision.

Not all the alternatives will match the results of the coronal brow lift; however, they are all far less invasive. Each alternative has its own benefits and limitations. Careful patient evaluation facilitates matching the patient to the best option (see Chapters 23 and 24).

SPECIFIC CLINICAL APPLICATIONS

Coronal Brow Lift

Despite the popularity of the endoscopic forehead lift (see Chapter 22), the coronal brow lift is an excellent option. Many surgeons consider it the method of choice for all patients; some surgeons limit the coronal lift to patients who are not candidates for an endoscopic approach.

This approach affords excellent exposure, facilitating release of periorbital septa and adhesions, muscle excision, and brow mobilization. Through scalp excision, the desired preplanned brow elevation and brow shaping can be achieved.

Indications and Contraindications

The coronal brow lift may be applied universally to anyone who is a candidate for forehead rejuvenation. It is my opinion that the best candidates are those who are not suitable for the endoscopic approach; these include patients with high foreheads, significant frontal bone convexity, a high or receding hairline, extremely thick skin or deep lines, and significant brow ptosis with excess skin over the lateral brow and glabella. Patients who would have similar results with less-invasive procedures would not be candidates for the coronal approach.

Preoperative Planning

Markings

As with other brow-lift procedures, the coronal brow lift is rarely performed in isolation. It is typically combined with other periorbital procedures or full facial rejuvenation. This is a full, open procedure; therefore preoperative markings are not as critical as the markings for the endoscopic approach. However, it is useful to mark the sentinel vein, the temporal crest, and the course of the supraorbital and supra-trochlear nerves.

Incisions

The incision will vary, depending on the patient's hairline and the desired results. There are three options for planning the incision: (1) a standard coronal incision, (2) a modified coronal incision, and (3) an anterior hairline incision.

The standard coronal incision is placed 6 to 8 cm behind the frontal hairline. It is easily concealed within the hair in patients with normal hair thickness. The modified coronal incision is curved anteriorly in the frontal area. This is best for individuals who have a normal temporal hairline but a very high frontal hairline. By modifying the incision and bringing it to the hairline in the frontal area, the height of the forehead may be reduced. The frontal portion of the incision may be visible. The anterior hairline incision is best reserved for an individual with a high forehead and a receding hairline in the temporal and frontal areas. In such individuals this incision allows reduction in the forehead height and temporal hairline. This entire scar may be visible, and most surgeons and patients prefer to avoid this incision. Any or all of these incisions, particularly the anterior hairline incision, may be made in a zigzag fashion to break up the resultant scar.

Vectors of fixation are also marked on the forehead; these will include a line projected onto the head from the most convex portion of the hair-bearing brow. These vectors are a guide to scalp excision and brow positioning.

Operative Technique

Although the procedure can be performed with either a local or a general anesthetic, our preference is general anesthesia, because other procedures are usually performed in combination. With the patient lying supine on the operating table, with the head slightly elevated to decrease venous engorgement, the hair is washed with soap and braided, and the proposed area of scalp excision may be shaved. The entire area is infiltrated with 0.5% lidocaine and epinephrine 1:200,000. The field is then prepared with povidone-iodine (Betadine) and draped.

After allowing sufficient time (8 to 10 minutes) for the epinephrine to take effect, the surgeon makes the incision through the scalp, down to the deep temporal fascia in the temporal area, and more centrally down to the periosteum. The knife blade is beveled so that it runs parallel with the hair roots to preserve as many hair follicles as possible. This is more critical with the modified and anterior hairline incisions. The anterior hairline incision is not made anterior to the hairline, as its name indicates, but must be made 1 or 2 mm behind the hairline so that some hair follicles are left within the cut edges.

Once the incision is made, the elevation of the forehead flap proceeds very rapidly in a bloodless field between the temporoparietal fascia and deep temporal fascia laterally and the subperiosteal plane centrally. The flap is elevated to the orbital rims. This elevation will release the periorbital septa and allow easy access to the glabellar musculature.

The anterior hairline approach will allow dissection in the subcutaneous plane. This subcutaneous plane is directly over the frontalis muscle. This allows significant reduction of transverse forehead lines through the release of the fibrous septa, which run between the muscle and the overlying skin. An added advantage of this approach is better preservation of the scalp's sensory innervation.

Once the flap is elevated, the corrugator, procerus, and depressor supercilii muscles are easily identified. The muscles are divided, avulsed, or cauterized, according to the surgeon's preference. To weaken the frontalis muscle, the lowest portions of the muscle are incised. The surgeon notes the course of the supratrochlear and supraorbital nerves and divides the frontalis muscle, carefully avoiding the nerves. A variety of techniques have been used to weaken the frontalis in this area, including horizontal division, crisscross division, and even a 1 cm strip excision. The scalp flap is then retracted superiorly and the degree of elevation is adjusted.

Next the scalp is incised at key sites, and fixation sutures or staples are placed. Usually the scalp is fixed at three sites: one centrally and one on each side, according to the preoperative vectors.

The intervening scalp is excised and closed in two layers with sutures and staples.

Postoperative Care

The patient's head is elevated, ice packs are placed over the eyes, and measures are taken to prevent an elevation in blood pressure and nausea and vomiting. Most patients undergoing a brow lift with additional procedures are kept overnight. Staples and sutures are removed 5 to 7 days postoperatively, and physical activities are restricted for 2 to 3 weeks.

Outcomes

This procedure has proved effective, with acceptable morbidity. The results have stood the test of time. Complications include alopecia, dysesthesias, and sensory loss in the scalp.

Direct Brow Lift

A direct brow lift is an effective method for elevating the brow, particularly the lateral brow. However, the direct lift is rarely used, because it may leave a visible scar. This approach offers excellent brow elevation through direct excision of the redundant skin. It will also allow access to the muscles. It is a quick, simple procedure that can be performed with a local anesthetic and carries minimal risk to the sensory nerves.

Indications and Contraindications

The best candidates are older individuals with heavy lateral brows and deep transverse forehead creases where the scar can be hidden. This is a relatively quick procedure and may be an acceptable alternative for patients who are not candidates for other options that require lengthier operations. The disadvantage is the scar.

Preoperative Planning

Markings and Incisions

The incision choices include an incision directly above the hair-bearing brow, which follows the shape of the brow, or an incision higher up, within a preexisting crease.

For the incision along the hair-bearing brow, a mark is made that follows the upper border of the hair-bearing brow. The skin above is then pinched to bring the brow into the proposed position, and the upper border of the skin excision is marked.

The design is varied to allow direct upward elevation of the brow (*left*) or lateral elevation (*right*). The incision within the crease is marked with the patient actively elevating the brow. The amount of forehead skin to be excised is then assessed and marked by pinching the forehead skin.

Operative Technique

The procedure is performed with a local anesthetic unless it is combined with other procedures.

Following the markings for a central brow elevation, the surgeon excises the predetermined skin. This is limited to a skin excision to avoid injury to the frontal branch of the facial nerve and the sensory nerves. (It is possible through the transverse incision to access the glabellar musculature; however, this is not commonly performed. This operation is usually limited to skin excision.)

The wound is then closed in two layers with 5-0 Monocryl sutures to the dermis, and the skin is closed with intracuticular Monocryl or simple 6-0 Prolene sutures.

Postoperative Care

Postoperative swelling is prolonged and noticeable. To minimize this, it is important to keep the patient's head elevated, with ice packs on the eyelids. We also consider the use of diuretics and a short course of methylprednisolone (Medrol Dose Pack).

Outcomes

The direct brow lift is an effective way of elevating the lateral brow. In carefully selected patients, the scar may be imperceptible.

Results

Courtesy Clinton D. McCord, Jr., MD

This elderly man underwent a direct brow lift with upper and lower lid blepharoplasties. His postoperative result shows lateral brow elevation with an imperceptible scar.

Transpalpebral Browpexy

The transpalpebral approach offers minimal lateral brow elevation through an upper lid blepharoplasty and is best as an adjunct to upper lid blepharoplasty rather than a primary brow-lift procedure.

Indications and Contraindications

The limited elevation seen with this approach limits its application to patients with mild lateral brow ptosis and with no medial brow ptosis or excess skin at the nasal radix.

Preoperative Planning

Markings

The brow is held in the projected position, and the upper eyelid is marked for an upper lid blepharoplasty.

Operative Technique

The incisions are made and the skin-muscle excision for the blepharoplasty is completed. The orbicularis muscle is retracted upward with two Blair retractors and with the cutting current and a Colorado tip. The dissection is continued deep to the orbicularis to the lateral orbital rim, staying above the periosteum. The dissection continues upward laterally for 2 to 3 cm. Care should be taken to preserve the sentinel vein, which is easily identified. This dissection releases some of the adhesions and septa of the lateral orbital area. The plane of dissection is deep to the course of the frontal branches of the facial nerve.

The calipers are then used to mark a point 5 to 10 mm above the orbital rim.

Then a 5-0 absorbable PDS or permanent clear nylon suture is used to fix the hair-bearing brow to the periosteum. The suture is first placed through the orbicularis, the retro-orbicularis oculi fat (ROOF), and the deep layers of the dermis, right in the middle of the hair-bearing brow. Next, the needle is passed through the previously marked periosteum. The suture is then tied, moving the brow upward. The eyelid skin is closed. Dimpling may result if the suture through the orbicularis and ROOF extends too far into the skin. Skin redundancy may result above the point of fixation if the lateral brow is inadequately undermined.

Postoperative Care

Postoperative care is the same as for upper lid blepharoplasty (see Chapter 28).

Outcomes

Only minimal elevation is possible with this technique. The results have been effective and maintained over time.

Results

This patient was seen in consultation for upper and lower lid blepharoplasty. He requested improvement of the heaviness of his upper eyelids and the excess skin and bags of his lower eyelids. In addition to excess skin in the upper lids and aging of the lower lids, he had lateral brow ptosis. He underwent upper and lower lid blepharoplasty with an internal transpalpebral browpexy. The split-view image shows his result at 2 years. Note the elevation of the brow through the internal browpexy suture.

Concluding Thoughts

The popularity and effectiveness of injectable neurotoxins has led to a decline in the number of brow lifts performed. Despite that, there is still a role for these alternative procedures. Patient selection and matching the procedure to the patient is the key. Although coronal brow lifts and direct brow lifts have limited application in my practice, the transpalpebral browpexy has proved very useful.

Clinical Caveats

Coronal Brow Lift

The surgeon can avoid creating a surprised look by limiting traction and scalp excision.

The incision line is beveled to preserve hair follicles.

The anterior hairline incision should be placed 1 to 2 mm behind the hairline to preserve hair roots rather than in front of the hairline.

Supraorbital and supratrochlear nerve branches should be preserved while dividing the frontalis muscle.

Direct Brow Lift

Incisions are best placed within preexisting creases.

The excision should be limited to skin only to avoid nerve injury.

Transpalpebral Browpexy

Dimpling can be avoided by limiting the suture placement to the deep dermis.

An overhang can be avoided by adequately undermining the lateral brow.

Annotated Bibliography

Friedland JA, Jacobson WM, Terkonda S. Safety and efficacy of combined upper blepharoplasties and open coronal browlift: a consecutive series of 600 patients. *Aesthetic Plast Surg* 20:453-462, 1996.

Many surgeons and several reports question the safety of blepharoplasty and open coronal foreheadplasty being performed concomitantly. The technique used in this series is presented in detail. The consistently excellent results obtained satisfy the aesthetic goals of both patients and surgeons—and suggest a renewed interest in the technique based on its simplicity and easily reproducible results.

Kaye BL. The forehead lift: a useful adjunct to face lift and blepharoplasty. *Plast Reconstr Surg* 60:161-171, 1977.

The forehead lift, with interruption of the continuity of the frontalis muscle, has been an effective method for improving the appearance of the upper third of the face. It can be done independently, or combined with facial rhytidectomy, blepharoplasty, and/or other ancillary procedures. In some cases of apparent upper lid redundancy, it can eliminate the need for upper lid blepharoplasty. The results are pleasing and seem to be lasting, while the complications have been few and mild. The authors describe the operation and discuss its indications, contraindications, advantages, and disadvantages.

Knize DM. Limited-incision forehead lift for eyebrow elevation to enhance upper blepharoplasty. *Plast Reconstr Surg* 97:1334-1342, 1996.

A forehead lift technique with temporal scalp incisions only 4.5 to 5.0 cm long can produce a result comparable with that of the coronal incision approach when combined with transpalpebral resection of the corrugator supercilii muscles and transection of the procerus muscle. This eyebrow elevation technique minimizes the risk of permanently injuring the supraorbital nerve branches that innervate the frontoparietal scalp and can effectively treat cases of advanced eyebrow ptosis. This forehead lift technique describes a method for determining the appropriate area of eyelid skin for excision when a forehead lift and upper blepharoplasty are performed concomitantly.

Knize DM. Transpalpebral approach to the corrugator supercilii and procerus muscles. *Plast Reconstr Surg* 95:52-60, 1995.

The author describes the most effective method for treating glabellar area skin contour irregularities produced by hyperactive corrugator supercilii and/or procerus muscles. A transpalpebral technique, performed on 40 patients who were followed for 6 to 24 months, is described, and the cadaver and nerve block studies on which this technique is based are discussed. The postoperative cosmetic improvement of the glabellar area is comparable in appearance to that achieved from a coronal incision approach.

Paul M. The evolution of the brow lift in aesthetic plastic surgery. *Plast Reconstr Surg* 108:1409-1424, 2001.

For nearly 100 years, aesthetic improvement of the aging face has included surgical elevation of the brow. Within the past decade, the minimal incision approach to brow lifting afforded with the endoscope radically changed surgical options in forehead rejuvenation. Further advances have added to these options and have provided a palette of alternatives in aesthetic correction of the upper third of the aging face.

CHAPTER 26

Applied Anatomy of the Eyelids and Orbit

MARK A. CODNER, MICHELLE B. LOCKE

The fundamental key to success in surgery of the eyelids and periorbital region is precise knowledge of the pertinent anatomy. The eyelids and periorbital area represent an anatomically complex and intricate region that contains a number of critical structures in close proximity to areas requiring surgical manipulation. The anatomy of the eyelids and orbit also influences the form, function, and appearance of the eyelids. Knowledge of the anatomy should include both the areas planned for surgical correction and the areas that can be secondarily affected by surgical manipulation or by complications.

Many of the new techniques for eyelid surgery have an anatomic basis that requires solid grounding in anatomy to ensure that these procedures are performed safely and to maximize the aesthetic and functional results. Furthermore, knowledge of the anatomy is required to avoid and treat complications that may occur after blepharoplasty. Numerous studies have contributed to defining the anatomy of the eyelids and orbit. Jelks and Zide described the anatomic structures encountered during blepharoplasty; Jelks and Jelks described vector analysis of the globe and infraorbital region to identify patients at risk for lid malposition after blepharoplasty. Additional clinical anatomic studies by Rees and LaTrenta discussed the morphologically prone eye in which the risk of dry-eye syndrome is increased after blepharoplasty. Hirmand et al used Hertel exophthalmometry preoperatively to identify patients with prominent eyes, who are at high risk of lid retraction and scleral show following blepharoplasty.

More recent anatomic studies have focused on the relationship between the lower eyelids and the midface, including the orbital septum described by Pessa, the orbicular ligament described by Kikkawa et al, and the anatomy of the malar mounds described by Mendelson and colleagues. Rohrich et al and Mendelson et al described the anatomic subcutaneous units of the periorbital region as well as the face, and the aging changes associated with these structures.

Structures of the Eyelids and Orbit

The eyelid is a bilamellar structure consisting of an anterior lamella and a posterior lamella. The anterior lamella consists of skin and the orbicularis oculi muscle; the posterior lamella includes the tarsoligamentous sling, which comprises the tarsal plate, the medial and lateral canthal tendons, the capsulopalpebral fascia, and conjunctiva. The septum is the dividing layer, which originates at the arcus marginalis along the orbital rim and inserts into the dermis, creating the upper and lower eyelid creases. The septum separates the anterior and posterior lamella, and is often referred to as the middle lamella. The horizontal interpalpebral fissure is formed by the lid margin and measures approximately 30 to 31 mm transversely and 8 to 10 mm vertically.

Normal eyelid surface anatomy

The lateral canthal angle is formed by the lateral commissure and is generally positioned approximately 2 mm superior to the medial canthus, giving the eyelid a slightly upward lateral inclination to the palpebral fissure (canthal tilt). The position of the lateral canthus, however, varies according to age, family traits, race, and sex. In primary gaze, the upper eyelid margin is positioned 1.5 mm inferior to the superior corneoscleral limbus, and the lower eyelid margin rests just at the inferior limbus of the cornea. The upper eyelid margin forms a smooth arch with the highest point positioned between the medial limbus and the pupil. With age, there is a gradual lateral shift of this point as the tarsal plate migrates laterally. The horizontal crease in the upper eyelid is formed by the dermal insertion of the levator aponeurosis after it passes through the orbicularis muscle. The eyelid fold is the excess skin and muscle that overhang the crease, which is a fixed line.

Prominent eye

The degree of eye prominence depends on the relationship between the globe and the bony orbit. This can be difficult to accurately assess clinically, because the soft tissue anatomy of the region can mask the bony landmarks. Preoperative assessment with Hertel exophthalmometry is the most reliable method. Normal protrusion is 15 to 17 mm and is slightly greater in black patients. This results in a negative vector to the globe-orbital rim relationship.

Both the upper lid crease and fold vary according to sex. The lid crease in the eyelid of an individual of European ancestry is approximately 7 mm above the lash margin at the midpupillary line in men and 10 mm above the lash margin in women. In the lower lid, there is an analogous eyelid crease 2 to 3 mm from the lash margin, which is more apparent in youth and diminishes with age. The Asian upper eyelid typically has a crease that is more inferior, often 3 to 4 mm above the lash margin, because of the low insertion of the septum, which allows preaponeurotic fat to migrate inferiorly into the pretarsal space.

Orbicularis Oculi Muscle

The orbicularis oculi muscle lies deep to the dermis, with minimal subcutaneous fat. The muscle is divided into three major portions: pretarsal, preseptal, and orbital. The pretarsal portion of the orbicularis is superficial to the tarsal plate and functions for lid closure during involuntary blinking. The pretarsal orbicularis is further subdivided into a superficial and a deep head. The preseptal orbicularis also has a

superficial and a deep component. In addition to controlling voluntary blinking, it functions as part of the lacrimal pump for tear drainage. The orbital orbicularis is the largest division of the orbicularis muscle and functions to protect the globe with forced eyelid closure as well as medial brow depression. The orbicularis oculi is a complex muscle that has multiple deep and superficial components. The origin of the orbicularis is from the medial canthus and medial orbit, whereas the insertion is at the lateral canthus and lateral orbit. The pretarsal fibers have a dense attachment to the upper and lower lid tarsal plates. The deep pretarsal muscle, Horner's muscle, originates at the posterior lacrimal crest, and the superficial pretarsal muscle originates from the anterior reflection of the medial canthal tendon, which originates from the frontal process of the maxillary bone. The lacrimal sac is clasped between the two heads. Both pretarsal orbicularis muscles insert laterally into Whitnall's tubercle, 1.5 mm inside the lateral orbital rim. Riolan's muscle is a dense group of pretarsal orbicularis muscles that form the subcutaneous component of the gray line along the lid margin. This is an important anatomic landmark that is used to realign the lateral canthus after canthoplasty.

The preseptal orbicularis also has a superficial and a deep component. The deep muscle, Jones's muscle, originates from the lacrimal sac fascia. The superficial preseptal muscle originates from the anterior reflection of the medial canthal tendon, along with the superficial pretarsal muscle. Both preseptal muscles insert onto the lateral palpebral raphe, which creates the superficial component of the lateral canthus. With each blink, contraction of Jones's muscle creates negative pressure in the tear sac, thereby draining the canalicular system. The lower lid orbital orbicularis originates from the maxilla, and the upper lid orbital orbicularis originates from the frontal bone converging on the superficial component of the medial canthal tendon. The lateral insertion of the orbital orbicularis creates the anterior raphe along the lateral orbital rim.

The 10 separate heads of the orbicularis oculi muscle all originate from the medial aspect of the orbit and insert along the lateral aspect of the orbit. Therefore the medial canthus represents the “business end” of the orbicularis muscle, including the dominant blood supply and innervation originating medially and contributing to the major contractile forces used for blinking, the lacrimal pump, and eye protection.

In contrast to the medial origin, the lateral insertion of the orbicularis oculi muscle simply acts as a lateral anchor with a deep and a superficial component forming the lateral canthal tendon and lateral orbital raphe. The lateral aspect of the orbicularis represents the fixed anchor point to the bony rim, which functions as a relatively stable fulcrum for the eyelids, thereby allowing the forces of medial contraction to change lid position. However, with extreme abduction of the globe, the lateral canthus can mobilize up to 2 mm.

Tarsoligamentous Sling

Whereas the skin and muscles comprise the anterior lamella, the tarsoligamentous sling creates the support structure for the posterior lamella. The tarsal plates constitute the connective tissue framework of the upper and lower eyelids. The upper lid tarsal plate is approximately 30 mm horizontally and 10 mm vertically at its widest dimension. Attachments to the upper lid tarsal plate include the pretarsal orbicularis and the levator aponeurosis on the anterior surface, Müller's muscle on the superior border, and conjunctiva on the posterior surface. The lower lid tarsal plate measures approximately 28 mm horizontally and 4 mm in vertical dimension. Attachments to the lower lid tarsal plate include the pretarsal orbicularis, capsulopalpebral fascia, and conjunctiva. The tarsal plates of the upper and lower eyelids are attached to the orbital rim by the medial and lateral canthal tendons and retinacular support structures. The canthal ligaments are the fibrous extensions of the tarsal plate, whereas the canthal tendons represent the insertion of the deep heads of the orbicularis oculi muscle to the bone, thereby constituting a true tendon.

The medial canthus is a complex structure that forms the medial fixation point for the medial commissure consisting of an anterior and posterior reflection of the medial canthal tendon as well as the medial retinaculum. The anterior reflection of the medial canthal tendon inserts on the anterior nasolacrimal crest formed by the frontal process of the maxilla and is anterior to the lacrimal sac. The posterior reflection of the medial canthal tendon is deep to the lacrimal sac and inserts on the posterior lacrimal crest on the lacrimal bone. The medial retinaculum is a complex structure formed by the deep head of the pretarsal orbicularis, the orbital septum, the medial extent of Lockwood's inferior suspensory ligament, the medial horn of the levator aponeurosis, the medial rectus cheek ligaments, and Whitnall's ligament. The medial retinaculum represents a fixed fulcrum point to maintain medial canthal position, allowing the orbicularis muscles to act on lid position rather than medial canthal position.

The lateral canthus also consists of a complex connective tissue framework that functions as an integral fixation point for the lower lid. The lateral canthal tendon, which is approximately 5 mm in length, is formed by fibrous crura which connect the tarsal plate to Whitnall's lateral orbital tubercle within the lateral orbital rim. In addition, the lateral retinaculum is formed by ligamentous structures from the lateral horn of the levator aponeurosis, lateral rectus cheek ligaments, Whitnall's suspensory ligament, and Lockwood's inferior suspensory ligament, which converge at the lateral canthal tendon. Although the lateral retinaculum represents the lateral point of fixation, there is some lateral mobility of the commissure during lateral gaze in order to increase the lateral visual field. This anatomic finding predisposes the lateral canthus to the development of laxity and phimosis or medial migration with age, as opposed to the medial canthus, which remains relatively fixed.

In addition to the tarsal plates and canthal tendons, support structures in the upper and lower eyelids stabilize the tarsoligamentous sling. The superior transverse ligament of Whitnall is partially formed by the fascia of levator palpebrae superioris. Whitnall's ligament has a medial insertion at the trochlea of the superior oblique and a lateral insertion at the lacrimal gland pseudocapsule and the frontal bone of the lacrimal sac fossa. The function of Whitnall's ligament is to act as a fulcrum to con-

vert the vector of pull of the levator palpebrae superioris muscle from a posterior vector originating from the lesser wing of the sphenoid to a superior vector in order to elevate the eyelid. Therefore Whitnall's ligament functions as an anatomic pulley or check ligament so that the upper lid does not pull away from the globe during opening. The lower eyelid has an analogous inferior suspensory ligament, Lockwood's ligament. Lockwood's ligament arises from the medial and lateral retinaculum and fuses with the capsulopalpebral fascia anterior to the inferior oblique muscle, prior to inserting on the inferior tarsal border. The arcuate expansion of Lockwood's ligament, Clifford's ligament, inserts into the inferolateral orbital rim and fuses with the interpad septum between the central and lateral fat compartments of the lower eyelid. The function of Lockwood's ligament is to stabilize the lower lid on downgaze, while the lower lid retractors cause lid depression of the eyelid to increase the inferior visual field during downgaze.

Upper Lid Retractors

Levator Palpebrae Superioris and Müller's Muscle

While the primary function of the orbicularis oculi muscle is to provide varying degrees of eyelid closure, the muscle antagonists located within the orbit function to open the eyelids. The upper eyelid retractors include the levator palpebrae superioris muscle and Müller's superior tarsal muscle. The levator muscle is striated muscle and is innervated by the superior division of the third cranial nerve. The levator muscle originates from the lesser wing of the sphenoid at the orbital apex and inserts along the anterior surface of the tarsal plate, stabilizing the pretarsal orbicularis muscle. The levator aponeurosis begins at the musculoaponeurotic junction, which is 10 to 14 mm below Whitnall's ligament and 5 to 7 mm above the superior border of the tarsal plate. The levator aponeurosis inserts into the dermis at the superior tarsal border and fuses with the septum to create the upper eyelid crease. Disinsertion of

the levator aponeurosis results in lid ptosis with descent of the tarsal plate and elevation of the lid crease. Inferior to Whitnall's ligament, the levator aponeurosis widens to form lateral and medial horns. The lateral horn divides the lacrimal gland into orbital and palpebral lobes, and inserts into the lateral orbital tubercle and lateral retinaculum as well as the capsulopalpebral fascia of the lower eyelid. The medial horn inserts into the posterior reflection of the medial canthal tendon. The function of the levator horns is to distribute the forces of the levator muscle equally along the aponeurosis, thereby allowing the majority of lid elevation to occur centrally.

In addition to the levator palpebrae superioris muscle, Müller's superior tarsal muscle contributes to eyelid opening. Müller's muscle is smooth muscle that originates from the posterior surface of the levator muscle and inserts into the superior tarsal border. Müller's muscle is innervated by the sympathetic nervous system from the superior cervical ganglion. Innervation passes through the cavernous sinus and optic canal to enter to orbit with the ophthalmic artery. As well as mechanical dehiscence of the levator aponeurosis, upper lid ptosis can be caused by abnormalities of the third cranial nerve resulting in levator muscle weakness or by loss of sympathetic nerve supply causing Müller's muscle weakness resulting in Horner's syndrome. Orbital Horner's syndrome from orbital apex tumor or trauma includes ptosis and meiosis, whereas Horner's syndrome from a Pancoast thoracic tumor includes ipsilateral anhydrosis to complete the triad.

Lower Lid Retractors

The lower lid retractors include the capsulopalpebral fascia and the inferior tarsal muscle, which are closely applied. The capsulopalpebral fascia originates from the inferior rectus fascia and splits to envelop the inferior oblique muscle. The capsulopalpebral fascia inserts into the inferior tarsal border and the dermis to create the lower eyelid crease. The capsulopalpebral fascia is lined by conjunctiva and the inferior tarsal muscle. The inferior tarsal muscle is smooth muscle innervated by the sympathetic nervous system, which functions to depress the lower lid on down gaze. In the lower eyelid the capsulopalpebral fascia is analogous to the levator aponeurosis in the upper lid, and the inferior tarsal muscle is analogous to Müller's muscle.

Orbital Septum

The orbital septum separates the anterior and posterior lamella, and helps maintain periorbital fat within the anatomic confines of the orbit. The orbital septum originates from an area of periosteal thickening called the arcus marginalis at the orbital rim. The orbital septum originates deep to the lacrimal sac along the posterior lacrimal crest and continues around the orbit in a spiral fashion passing deep to Whitnall's tubercle at the level of the lateral orbital rim. Inferomedially, the septum originates from the anterior lacrimal crest. It is therefore discontinuous at the medial canthus. In the upper eyelid, the septum fuses with the levator aponeurosis approximately 2 to 3 mm above the tarsal plate. In the lower lid, the septum fuses with the capsulopalpebral fascia just below the tarsal plate. There are numerous additional interpad and intrapad septal structures, which separate the central and nasal fat pad in the upper eyelid and the central and lateral fat pad in the lower eyelid.

Appreciation of the anatomy of the septum is important, particularly when surgical procedures such as resetting, tightening, or excising the septum are considered. A rare cause of blindness following blepharoplasty is retrobulbar hematoma, also known as acute orbital compartment syndrome. The globe and retrobulbar contents are enclosed within a relatively rigid cone, with bony walls to the orbit laterally and posteriorly, and the inexpandable orbital septum anteriorly. Therefore any increase in orbital content volume increases pressure in the compartment and decreases tissue perfusion. This can occur following blepharoplasty due to postseptal bleeding from orbital vessels and can lead to blindness if not promptly treated. In 2004 Hass et al published results of a survey of members of the American Society of Ophthalmic, Plastic and Reconstructive Surgeons (ASOPRS) to ascertain the incidence of retrobulbar hematoma following blepharoplasty. The reported incidence was 0.055% (149 of 269,433 patients), and the reported rate of permanent visual loss following this was 0.0045% (12 patients). Most cases occurred within 3 hours, with 96% occurring by 24 hours. Hemorrhage was commonly associated with Valsalva-type maneuvers such as coughing or vomiting.

Orbital Fat Pads

Posterior to the orbital septum, the periorbital fat pads play an important role in both upper and lower blepharoplasty. There are two main fat pads in the upper eyelid and three fat pads in the lower eyelid. The two upper fat pads are referred to as the central and nasal fat pads, which are located in the preaponeurotic space just anterior to the levator aponeurosis. The interpad septum arises from the orbital septum and inserts into the levator aponeurosis. It separates the central and nasal fat pads and is continuous with a septal fascial connection to the trochlea. The nasal fat pad has been shown to be more fibrous and is pale in color compared to the more yellow colored central fat pad.

The intrapad septum separates the nasal fat into two compartments. The medial palpebral artery is located in the inferior nasal compartment and can contribute to significant bleeding during blepharoplasty. The central fat pad is superficial to the levator aponeurosis, in the preaponeurotic space, and contributes to the fullness of the upper lid fold. Histologically, the nasal fat pad has larger fat globules, and the central fat pad has more intrapad septa and finer blood vessels. These differences are thought to be due to different embryologic origins as well as different fatty acid constituents of the nasal and central fat pads.

Although the lateral compartment of the upper eyelid consists of the lacrimal gland, studies have shown that a lateral extension of the central preaponeurotic fat pad extends to the lateral upper compartment in 15% to 20% of patients. The lateral extension of the central fat pad is anterior to the orbital lobe of the lacrimal gland and can be easily dissected away from the gland. The lacrimal gland lacks a true capsule, and is divided into the orbital and palpebral lobes by the lateral horn of the levator. The orbital lobe is positioned in the fossa glandulae lacrimalis, which is a shallow fossa in the frontal bone at the superolateral orbit. The smaller palpebral lobe is connected to the orbital lobe by an isthmus posterior to the lateral horn of the levator muscle. Lacrimal gland ptosis is caused by dehiscence of Sommering's ligaments, which are the fibrous interlobular septa that connect the gland to the orbital rim fossa. Fullness in the lateral aspect of the upper eyelid is often caused by lacrimal gland ptosis. Lateral to the lacrimal gland is a separate compartment just above Whitnall's tubercle. Eisler's pocket, which was described by Kestinbaum, is formed by the space created by the septum and the lateral canthal tendon inserting on Whitnall's tubercle. Eisler's fat pad is a small accessory fat pad located in Eisler's pocket, which serves as a useful anatomic landmark for Whitnall's tubercle. The location of this fat pad is clinically useful during placement of the lateral canthoplasty suture.

There are three fat pockets in the lower eyelid: central, nasal, and lateral. The nasal compartment in the lower eyelid is similar in makeup to the nasal compartment of the upper eyelid with more fibrous, pale fat. The inferior oblique muscle is commonly visible during blepharoplasty and separates the nasal and central fat compartments. The central and lateral fat compartments are separated by an interpad septum as well as a fascial extension from Lockwood's ligament, the arcuate expansion. Recent MRI imaging of the orbit has demonstrated an increase in the total orbital fat volume with age, particularly in the central and lateral regions. This increase was not seen anterior to the orbital rim. Darcy et al think that increased fat volume is a contributing factor to increased lower lid prominence with age and support the removal of fat from the central and lateral compartments during blepharoplasty. The arcuate expansion of Lockwood's ligament should be preserved during lower lid dissection to maintain lateral support. Because the nasal and central fat pads envelop the inferior oblique muscle, aggressive fat transposition techniques that suture the

fat below the rim can result in diplopia from impaired inferior oblique function from a lasso effect. The lateral extent of the lateral fat pocket includes the lateral retinaculum and lateral canthal tendon.

The most posterior layer of the eyelid is the conjunctival lining, which reflects on itself at the fornix and covers Tenon's capsule. The palpebral portion of the conjunctiva is closely adherent to the posterior surface of the tarsal plate and the lid retractors. At the fornix, the conjunctiva becomes bulbar conjunctiva overlying the globe to the corneoscleral limbus. Small accessory glands are located within the conjunctiva, creating the aqueous portion of the tear film.

The cross-sectional anatomy of the eyelid and periorbital region demonstrates the creation of the upper lid crease formed by the fusion of the orbital septum, levator aponeurosis, and upper lid dermis. The anatomy of the lower eyelid fornix is clinically important because the transconjunctival approach to blepharoplasty is often used. The orbital fat can be removed by a transeptal (preseptal) approach, which divides the conjunctiva, capsulopalpebral fascia, and septum, or by a retroseptal (postseptal) incision through the conjunctiva and capsulopalpebral fascia, leaving the septum intact.

Neurovascular Supply

Motor Innervation

The motor innervation to the orbicularis oculi muscle is quite diffuse, with contributions from multiple branches of the facial nerve, including the frontal, zygomatic, and buccal branches. The major nerve supply enters the medial aspect of the orbicularis, along with an additional supply laterally. The terminal muscles innervated by the frontal branch include the frontalis muscle and the transverse head of the corrugator supercilii. Additionally, the frontal branch provides innervation to the upper lid pretarsal and preseptal divisions of orbicularis, which are noted clinically by the presence of a weakened blink after frontal branch injury. The terminal muscles innervated by the zygomatic branch of the facial nerve include the zygomaticus major and the oblique head of the corrugator muscle. The buccal branch of the facial nerve innervates the terminal facial mimetic muscles medially and the procerus muscle.

Cadaveric dissection reveals a diffuse plexus of nerves innervating the orbicularis oculi muscle. These branches pass both superficial to the origin of the zygomaticus major supplying the lateral orbicularis and deep to the zygomaticus major continuing to supply the medial orbicularis.

The buccal branch also supplies a diffuse plexus of nerve branches to the medial palpebral orbicularis, including the deep heads in both the upper and lower eyelid that contribute to voluntary and involuntary lid closure. This is clinically evident by impaired upper eyelid closure after an isolated medial lower lid incision over the nasolacrimal crest following dacryocystorhinostomy (DCR) or Mohs surgery, despite the absence of an upper lid incision.

Sensory Innervation

Sensory innervation of the eyelids arises from the ophthalmic and maxillary divisions of the trigeminal nerve. Upper lid sensory impulses are transmitted through supratrochlear, supraorbital, and lacrimal nerves, which are branches of the ophthalmic division. The ophthalmic nerve also provides sensation to the medial portions of the upper and lower eyelids by the infratrochlear branch. The major sensory input to the lower lid is from the infraorbital nerve, which is a major branch of the maxillary nerve. The remainder of the lower lid receives sensory input from the zygomaticofacial branch and the zygomaticotemporal branch of the maxillary nerve.

Arterial Supply

A dual arterial supply to the eyelids exists, which arises from both the internal carotid and external carotid system. The dominant supply arises medially. The internal carotid artery provides the blood supply to the orbit from the ophthalmic artery, which exits the orbit medially at the dorsal nasal and medial palpebral vessels, and exits the orbit superiorly at the supratrochlear and supraorbital arteries. Branches from the lacrimal artery, a branch of the ophthalmic artery given off in the orbital apex, provide the blood supply to the lateral aspect of the orbit. The internal and external carotid systems communicate through multiple arterial anastomoses. There are three main divisions: medial, central, and lateral. The medial blood supply from the external carotid system includes the facial and angular vessels, which anastomose with the dorsal nasal artery from the internal carotid. The central blood supply is provided by the internal maxillary and infraorbital vessels. The lateral blood supply is from the superficial temporal, transverse facial, deep temporal, and zygomaticofacial branches.

The blood supply to the upper lid margin includes two arcades, the superior tarsal arcade and the marginal arcade, which are branches of the medial palpebral and lacrimal arteries. The superior tarsal arcade is located superior to the border of the tarsal plate between Müller's muscle and the levator aponeurosis. The lower eyelid has a single inferior palpebral arcade along the lid margin just below the tarsal plate supplied by the medial and lateral inferior palpebral arteries, and including an anastomosis with the infraorbital artery from the external carotid system. Thus both lids have a dual blood supply from the medial and lateral aspects, allowing safe lateral canthotomy with preservation of the dominant blood supply from the medial inferior palpebral artery.

An understanding of the arterial anatomy of the eyelid and orbit is particularly important because a rare cause of blindness after blepharoplasty is periorbital arterial injection. Blindness can occur with inadvertent injections to the supraorbital or supratrochlear vessels, with retrograde flow into the ophthalmic artery causing central retinal artery embolization; this includes periorbital injection of fillers. A second cause of blindness is retrobulbar hematoma, which results in increased pressure behind the globe, causing central retinal artery occlusion.

Venous Drainage

Similar to the arterial system, venous drainage of the eyelid and periorbital region includes a dual superficial and deep system. The external periorbital area is drained by the internal jugular vein from branches including the anterior facial vein, superficial temporal vein, and external jugular vein. The central orbital area is drained into the cavernous sinus from branches including the superior ophthalmic vein, anterior ophthalmic vein, and pterygoid plexus.

Lymphatic Drainage

The lymphatic drainage of the upper and lower eyelids includes dual drainage to the preauricular parotid nodes and the submandibular lymph nodes. The upper eyelid, lateral canthus, and lateral half of the lower eyelid lymphatic vessels drain to the preauricular lymph nodes. The nasal aspect of the upper and lower eyelids and the

medial canthus have lymphatic drainage along the facial vein, then inferiorly to the submandibular lymph nodes. Lymphatic drainage is clinically relevant both as a contributing factor to the formation of chemosis after blepharoplasty and for potential metastatic spread of malignant neoplasms or infection involving the periorbital region.

Midfacial Anatomy

The anatomic relationship between the lower eyelid and the midface must be appreciated because changes in midface anatomy influence the appearance of the lower eyelid. In addition to the periorbital fat compartments, two additional fatty layers exist in the midface. Deep to the orbicularis oculi muscle is the suborbicularis oculi fat (SOOF). This layer is readily appreciated after suborbicularis dissection below the infraorbital rim. As the arcus marginalis is encountered and subsequently traversed, the SOOF becomes apparent between the overlying orbital portion of the orbicularis and the underlying soft tissue structures of the midface including facial mimetic muscles. The SOOF may be compartmentalized by septa into vertical and horizontal components, and the upper lid SOOF is divided into medial and lateral compartments. These septa may have a role in the regional blood supply, as vascular supply to the skin of the face is thought to be carried in the intercompartmental septa. The SOOF's greatest thickness and volume is lateral to the infraorbital foramen. The SOOF is deep to the superficial musculoaponeurotic system (SMAS) and also envelops the zygomaticus major and minor muscles. In addition to the SOOF, the malar fat pad is a triangular pad in the midface area, which is in the subcutaneous plane superficial to the SMAS. The midface presents with aging caused by the descent of the malar fat pad, which often unmasks the orbital fat pads as a result of inferior migration and thinning of the overlying tissue. The periorbital fat becomes visible, with pseudoherniation of the orbital septum.

It is not only soft tissue changes that occur with age; assessment of the human skull collection at the Smithsonian Institution suggests that progressive remodeling and retrusion of the orbital rim occurs throughout life. Others have found that while retrusion of the midface relative to the upper face does occur with age, this change happens below the level of the infraorbital rim. The exact manner of age-related bone change differs among patients, but overall, aging does remodel the orbital region and seems to increase the negative vector in older patients.

This cross-section of the periorbital anatomy illustrates the fat compartments, supporting ligaments, prezygomatic space, and subzygomatic space. In 1996 Kikkawa et al described a major supporting structure of the midface, the orbitomalar ligament, as the primary retaining ligament of the midface. It was thought to be an osseocutaneous ligament that originated at the inferior orbital rim just below the arcus marginalis and to penetrate the orbicularis oculi muscle anteriorly, inserting into the dermis. Muzaffar et al applied the more commonly used nomenclature, orbicularis retaining ligament (ORL), in 2002. Mendelson and colleagues further delineated this region in cadaver dissections and specified that there is a direct attachment of orbicularis oculi muscle to the orbital rim inferomedially, from the anterior lacrimal crest to about the level of the medial corneoscleral limbus. Farther laterally, the ORL provides an indirect attachment from the undersurface of the orbicularis oculi muscle to the orbital rim as far as the lateral canthal region, where it blends with the lateral orbital thickening. In its lateral section, the ORL lies directly orbital to the zygomaticofacial nerve, which is a reliable landmark for its location. The ORL is similarly continuous in the upper eyelid, from the medial to the lateral orbit. The orbital septum inserts into the most marginal part of the orbital rim, with the ORL inserting 2 to 3 mm outside this point. The merging of these two structures at their insertion forms the arcus marginalis. The prezygomatic space is the soft tissue area overlying the skeleton of the midface, namely the zygoma and maxilla. The infrazygomatic space covers the vestibule of the oral cavity.

The orbitomalar ligament contributes to formation of the malar crescent and malar bag, which are common findings with midface aging. Laxity of the ORL with age allows descent of the central fat pad and the lid-cheek junction. Descent is more prominent lateral than medially due to the direct attachment of the orbicularis oculi muscle to the orbital rim medially. In addition, the orbitomalar ligament contributes to the formation of the lid-cheek junction.

The orbitomalar ligament along with the origin of the levator labii superioris and levator alaeque nasi muscles contribute to formation of the tear trough. The anatomy of the tear trough is complex, with contributions from bone, muscle, and overlying soft tissue. The concavity begins at the anterior nasal lacrimal crest and is formed by the arcus marginalis, orbitomalar ligament, origin of the orbicularis oculi muscle, levator labii superioris, and levator alaeque nasi muscles inferiorly. With aging changes, descent of the SOOF contributes to attenuation of the overlying soft tissue, thereby unmasking the nasojugal groove. As mentioned, the ORL attaches to the orbicularis oculi at the junction of the infraorbital rim, and the division of the orbicularis retaining ligament provides mobilization of the SOOF and separates the prezygomatic space from the preseptal space. Appreciation of the anatomy of the midface is important when techniques are used to correct midfacial aging.

Annotated Bibliography

Hamra ST. The zygorbicular dissection in composite rhytidectomy: an ideal midface plane. *Plast Reconstr Surg* 102:1646-1657, 1998.

Composite rhytidectomy adds repositioning of the orbicularis oculi muscle to the deep plane face lift to achieve a more harmonious appearance of the face by adding periorbital rejuvenation. These two modifications allow a more predictable and impressive result. They reinforce the concept of periorbital rejuvenation as an integral part of facial rejuvenation, which produces a more harmonious immediate result and prevents the possible unfavorable sequelae of conventional rhytidectomy and lower blepharoplasty.

Jelks GW, Jelks EB. The influence of orbital and eyelid anatomy on the palpebral aperture. *Clin Plast Surg* 18:183-195, 1991.

This article discusses the multitude of factors influencing the palpebral aperture. Unique individual combinations of the orbital anatomic influences cause the variations in the palpebral apertures.

Mendelson BC, Hartley W, Scott M, et al. Age-related changes of the orbit and midcheek and the implications for facial rejuvenation. *Aesthetic Plast Surg* 31:419-423, 2007.

This paper describes the anatomy of the soft tissue and bony orbit. Changes that occur during the aging process are discussed. CT imaging was performed in three groups of patients of both sexes and different ages ranging from 21 to 70. Bony changes occurred that demonstrated retrusion of the anterior maxillary wall, which may contribute to midfacial aging.

Mendelson BC, Muzaffar AR, Adams WP. Surgical anatomy of the midcheek and malar mounds. *Plast Reconstr Surg* 110:885-896; discussion 897-911, 2002.

The authors describe the anatomy of the midcheek to explain midcheek aging and malar mounds. A cadaver study located a glide plane space overlying the body of the zygoma. Together the function of this space, as well as the anatomic boundaries and anatomic features of this area, determine the characteristic aging changes that occur in this region and explain malar mounds. The authors discuss the surgical implications resulting from this anatomy.

Muzaffar AR, Mendelson BC, Adams WP. Surgical anatomy of the ligamentous attachments of the lower lid and lateral canthus. *Plast Reconstr Surg* 110:873-884; discussion 897-911, 2002.

The authors describe the surgical anatomy of the superficial fascia of the face, which must include its deep attachments. Release of the deep ligamentous attachments (lateral orbital thickening and orbicularis retaining ligament) of the orbicularis fascia is important in some canthopexy and in rejuvenation procedures. The release allows effective redraping and upward mobilization of the orbicularis of the lower lid and the premalar soft tissues.

CHAPTER 27

Clinical Decision-Making in Aesthetic Eyelid Surgery

FOAD NAHAI

Evaluation

The hallmark of youthful-appearing eyelids is a smooth contour that extends from the brow to the upper lid and from the lower lid to the cheek and midface. The lid-cheek junction lies over the infraorbital rim and is usually 5 to 12 mm below the lid margin. The skin is tight and the tissues are full. There is an upward slant from the medial canthus to the lateral canthus, and eyelid tone is normal: a snapback test results in rapid lid recovery, and lid distraction will be 6 mm or less.

In contrast, the aged eye appears hollow, with a definite demarcation from the brow to the upper lid and the lower lid to the cheek and midface. In most individuals, the eye fissure becomes smaller and rounder with age. The lid-cheek junction lies well below the infraorbital rim, 15 to 18 mm from the lid margin. There is a downward slant from the medial canthus to the lateral canthus and eyelid tone is significantly

reduced, with a very slow result to the lid snapback test and a lid distraction of 6 mm or greater. (See Chapter 28 for further discussion of evaluation of the aged eye.)

These aging changes, which develop gradually over time, are a combination of volume loss, loss of skin elasticity, and downward descent of the tissues. These changes are classified into the following four types:

Type I: Aging confined to the lower lid, with skin and muscle laxity and pseudoherniation of the fat

Type II: Aging no longer confined to the lower lid; in addition to skin and muscle laxity, there is skin excess and minimal descent of the lid-cheek junction

Type III: Lower lid aging with volume loss, descent of the lid-cheek junction and malar eminence; skeletonization of the orbital rim and deepening of the nasolabial fold, loss of skin elasticity and lid laxity are also common findings

Type IV: Further volume loss and descent of the lid-cheek junction; deepening of the nasojugal groove; presence of malar bags; further loss of skin elasticity, lateral canthal descent and lid laxity with scleral show

This classification is most useful in selecting appropriate procedures to address specific problems for each patient type. In addition to addressing the lower eyelid, it also demonstrates that aging of the lower lid and midface are intertwined. Rejuvenation of one without the other will lead to a suboptimal or patchwork result. Concomitant with the aging changes of the lower lid and lid-cheek junction, there is a real or apparent loss of volume that must be addressed.

A component evaluation of the eyelids to determine aesthetic options will also minimize complications. Components of eyelid evaluation are discussed next.

Decision-Making Factors in Eyelid Surgery	
<i>Aesthetic Factors</i>	<i>Safety Factors</i>
Skin	Upper lid ptosis
– Quality	Lid tone
– Quantity	Eye prominence
Muscle	Canthal position
Fat	
Lid-cheek interface	
Scleral triangles	
– Medial	
– Lateral	

Skin

As an individual ages, the elasticity of eyelid skin diminishes, causing the skin to appear loose and wrinkled. There is real or apparent skin excess. The physician evaluates the quality and quantity of the skin. In assessing upper eyelid skin excess, the brow should be held in its ideal position. The eyelids should always be evaluated with the eyes open as well as shut.

Muscle

Muscle activity and morphology are noted. With aging, the orbicularis oculi muscle may become lax and hypertrophic, especially in the pretarsal area. Infratarsal fullness may also be present. Although this fullness is often associated with a youthful eye, some patients are concerned about infratarsal fullness.

Fat

Two pockets of periorbital fat are contained within the upper lid, with three in the lower lid. The surgeon notes these and decides whether to preserve, redistribute, or remove this fat. In addition, the retroorbicularis oculi fat (ROOF) lying along the lateral orbital rim between the orbicularis oculi muscle and the periosteum is also assessed. Under rare circumstances, some of this fat will need to be resected to improve the contour of the lateral orbital rim.

Upper Lid Ptosis

The presence or absence of upper lid ptosis should always be recorded. If present, it is pointed out to the patient and plans are discussed to correct it at the time of blepharoplasty.

Lid Tone

Lower eyelid tone is evaluated with the lid distraction test and lid snapback test. Routine correction of lower lid laxity is essential to minimize complications.

Eye Prominence (Hertel Measurement)

Eye prominence is assessed by means of the Hertel exophthalmometer, which measures the distance between the cornea and the lateral orbital rim.

Normal eye prominence, which is seen in 65% of the population, ranges from 15 to 17 mm. Deep-set or anophthalmic eyes measure less than 15 mm, and any measurement of 18 mm or greater indicates a prominent eye. These measurements play a significant role in determining risk, procedure selection, and lid-anchoring techniques.

Canthal Position

The surgeon notes the position of the lateral canthus in relation to the medial canthus. The lateral canthus should normally be higher than the medial canthus. A lateral canthus at the same level or lower than the medial canthus indicates significant lid laxity, requiring horizontal lid shortening (canthoplasty).

Scleral Triangles

The triangle between the cornea and the medial canthus is called the *medial scleral triangle*, and the triangle between the cornea and lateral canthus is called the *lateral scleral triangle*. With increasing lid laxity and age, these triangles, especially the lateral scleral triangle, are lost. Eye shape is judged by the shape and size of the lateral scleral triangle. The tighter the triangle, the more almond-shaped the eye; conversely, the looser the triangle, the rounder the shape of the eye.

Evaluation of skin, muscle, and fat plays a role in selecting the best treatment option. However, of more importance is evaluation of the lid-cheek interface and mid-face aging for lower lid options. For the upper eyelid, the relationship between the upper lid and the brow is an important determining factor.

Evaluation of lid tone, eye prominence, and canthal position plays a pivotal role in determining which lid-anchoring procedure is appropriate to minimize the potential for complications.

Preoperative Planning

27-1 Upper and lower blepharoplasty and midface cheek lift

Treatment Options

A variety of surgical and nonsurgical options are available for treating upper and lower eyelid aging. Fat grafting and injectables offer volume restoration of the upper lid and the lid-cheek junction. Surgical options include transcutaneous and transconjunctival approaches. Procedures range from the simple transconjunctival removal of fat from both upper and lower lids to complex procedures, including transpalpebral procerus corrugator muscle modification and browpexy through the upper eyelid and transpalpebral midface lift through the lower eyelid.

Options for Fat Management

In recent years there has been a tremendous revolution in our thinking and approach to facial rejuvenation. This is especially true in concepts of fat preservation and augmentation, not only in face lifts but even more so in blepharoplasty. Gone is the standard skin, muscle, and fat excision blepharoplasty that I was taught many years ago. Our current choices are to preserve or redistribute the periorbital fat and occasionally remove or even augment the fat. For augmentation, options include autologous fat, autologous dermis, fillers, and even alloplastic materials.

I base my options for fat management on evaluation of the lid-cheek junction and choose a procedure to improve this area.

Although most surgeons continue to rejuvenate the lower lid surgically, injectable fillers are being established as a safe and effective option for lower lid rejuvenation, especially for correction of the tear-trough area.

Options for Fat Management

Preserve	Augment
Redistribute	Remove

If the patient has an adequate volume of fat, my preferred technique for improving the lid-cheek junction is a combination of fat redraping and a transpalpebral midface lift with orbicularis muscle flap redraping. If the patient does not have fat herniation or enough fat for redraping, I plan no fat manipulation, I do not open the periorbital septum, and I rely on the transpalpebral midface lift and on orbicularis muscle flap redraping.

If I think that these approaches are not adequate for correction of the lid-cheek junction, I consider autologous tissue augmentation. I have no experience with alloplastic implants around the orbital rim, and I think that autologous tissue is as effective. Occasionally, I do resect fat from the lower lid, most often from the lateral compartment when the fat bulges out. Both of the patients above have undergone periorbital rejuvenation. The patient at the top of the page had no fat removal from either lower eyelid. The patient immediately above had fat removed only from the lower left eyelid.

A review of a personal series of 100 consecutive blepharoplasties revealed 49% with fat redraping, 38% with no fat manipulation, 9% with fat excision, and 4% with autologous grafting in the lower lid. In the upper eyelid in the same series, I resected fat from the medial nasal pocket in 76% and from the lateral pocket in only 24% of cases. These numbers are indicative of my current practice and the continuing trend toward fat preservation and fat augmentation in the periorbital area.

Resection of the ROOF was very popular several years ago and was part of my approach to the upper eyelid and lateral brow in selected patients. Today, with a better understanding of the aging process and the role of volume, I do not resect the ROOF. Patients with a full subcutaneous pocket deep to the lateral hair-bearing brow who would benefit from ROOF resection are few and far between.

With the current interest in fat preservation and adding volume to the lower eyelid, it is possible that the surgeon may injudiciously inject excessive amounts of autologous fat into the periorbital area, as is demonstrated in this patient. Given the unpredictability of the survival of the grafted fat, this is not an uncommon finding. Transconjunctival and transcutaneous fat removal has proved to be a relatively straightforward and effective procedure for correction of this problem. The injected fat bears little resemblance to the periorbital fat and maintains the appearance and morphologic character of the area from which it was harvested.

The transcutaneous approach was chosen for this patient so that her lid retraction and skin excess could be addressed, along with removal of excess injected fat.

Transconjunctival fat removal is shown in another patient.

Upper Eyelid

Options for upper eyelid rejuvenation are fewer than those for the lower eyelid. Most upper eyelids are approached through a standard skin-muscle incision. Rarely, the transconjunctival approach is an option to resect excess fat in the medial pocket. A skin excision with muscle preservation may sometimes be the best option to preserve orbicularis muscle to maintain volume in the upper eyelid.

Options for Upper Eyelid Rejuvenation

- Transconjunctival fat removal from the medial pocket
- Skin and muscle excision
 - Gateway to the lateral brow
 - Gateway to the glabellar muscles
 - Ptosis repair
- Skin excision with muscle and fat preservation

Options for rejuvenating the upper eyelid include transconjunctival and transcutaneous approaches. The transconjunctival approach has a limited role, confined to excision of fat from the medial or nasal fat pocket. The most versatile approach to the upper lid is excision of skin and muscle (the *open-sky* approach), which allows access to the periorbital fat, ROOF, lateral brow, glabellar muscles, and levator muscle. Recently the skin excision with muscle preservation approach to the upper eyelid has been popularized. With this volume-preserving procedure, the orbicularis is preserved to increase the volume of the upper eyelid. Access deep to the orbicularis is possible by merely dividing the muscle rather than resecting it.

Options for Upper Eyelid Rejuvenation

Components	Trans-conjunctival	Skin and Muscle Excision	Skin Excision
Skin	—	++++	++++
Muscle	—	++++	—
Fat	++++ (medial pocket only)	++++	—
Lateral brow	—	++++	—
Glabellar muscles	NA	++++	—
Ptosis repair	NA	++++	—

Degree of effectiveness indicated by the number of pluses.
NA, Not applicable.

Transconjunctival Approach

The transconjunctival approach has limited application for removal of the medial or nasal fat pocket only. I have found this to be a safe, efficacious technique in primary as well as secondary fat removal from the medial pocket. Ideal candidates have a bulging medial fat pocket of the upper eyelid with no excess upper eyelid skin.

The lateral fat pocket, preaponeurotic fat, in the upper eyelid lies anterior to the levator aponeurosis, whereas the medial or nasal fat pocket lies medial to the aponeurosis.

The insertion of the levator aponeurosis into the tarsal plate prevents herniation of the lateral fat pocket; however, the medial horn of the levator aponeurosis is much higher than the lateral horn. This allows herniation of the medial fat and access to the medial fat through the conjunctiva. The incision is made in the conjunctiva medial to the medial border of the tarsal plate.

The advantage of this transconjunctival approach is that it eliminates the need for an incision in the upper eyelid skin. This approach has been free of complications in my hands, and I have not seen any ptosis. The limitation of this approach is that only one aspect of upper eyelid aging—medial fat herniation—is addressed.

Skin-Muscle Excision

Skin-muscle excision is the most versatile approach to the upper eyelid, allowing manipulation and excision of fat from both periorbital fat pockets, excision of ROOF, if indicated, access to the lateral brow, and access to the glabellar muscles. The skin-muscle excision approach also affords exposure of the levator and its aponeurosis for ptosis repair. It is a proven approach with minimal morbidity. Potential problems include inadvertent disruption of the levator aponeurosis, leading to postoperative ptosis, and misplaced scars.

Skin Excision

In keeping with recent trends to preserve and restore volume in facial rejuvenation, a volume-preserving upper lid skin excision has been described (Fagien). If access deep to the orbicularis is needed, the orbicularis is divided rather than resected. It is thought that the small amount of orbicularis that is spared with this approach adds volume to the upper lid.

Lower Eyelid

My approach to the lower eyelid is based on management of fat, skin, muscle, and the lid-cheek junction. Options include the transconjunctival and transcutaneous approaches. A detailed evaluation of the eyelid and periorbital area helps to determine the appropriate selection of surgical technique. A variety of procedures are available to manage the skin laxity and excess, periorbital fat, muscle, and the lid-cheek interface and lid laxity. Some are relatively straightforward with minimal if any morbidity (for example, skin-pinch blepharoplasty and transconjunctival fat removal), whereas others, especially those designed to improve on the lid-cheek junction, are not only complex and technically demanding but also may lead to lid retraction and exposure. Correction of lid laxity and routine lid anchoring at the time of the primary procedure are prerequisites to minimize these potential complications.

The lid-cheek junction can be improved and the lower lid rejuvenated through manipulation of the SMAS with open face-lift procedures, such as the high SMAS technique, SMASectomy, and the extended MACS-lift technique with a skin-pinch blepharoplasty. Although all of these will improve on the lower lid, in my experience the results do not match those of a skin-muscle flap blepharoplasty approach.

Options for Lower Eyelid Rejuvenation

- Fillers
- Pinch blepharoplasty
- Transconjunctival fat removal
- Transconjunctival fat redistribution
- Transcutaneous
 - Skin flap
 - Skin-muscle flap
 - Fat management
 - Orbicularis redraping
- Midface Lift
 - Full open approach
 - Limited or endoscopic approach
- Certain face-lift techniques

Fillers

Autologous fat as a filler in the periorbital area is increasing in popularity and effectiveness (see Chapter 13). A variety of fillers, including nonanimal stabilized hyaluronic acid fillers (NASHAs), porcine collagen, and the semipermanent Radiesse are available for volume restoration of the lower lid, especially the nasojugal groove (see Chapter 12).

Pinch Blepharoplasty

The pinch technique is safe and effective for removal of excess, inelastic eyelid skin without disturbing the underlying orbicularis muscle. Although it has a role as a stand-alone procedure, a pinch blepharoplasty may be combined with transconjunctival fat removal from the lower lid. It may also be used as an adjunct to face-lift procedures such as the extended MACS-lift, which elevates the midface, resulting in excess lower lid skin. Although a canthopexy can be performed with a skin-pinch blepharoplasty, it is not imperative.

The excess eyelid skin is pinched with one pair of pickups in the left hand while the second pair of pickups in the right hand progressively pinches and squeezes the extra skin, proceeding from lateral to medial.

This “pinched” skin is then trimmed with a pair of scissors.

The skin excision is completed.

Because the skin has been pinched, there is very little bleeding after the skin excision. By spreading the skin, the extent of the resection can be seen, and bleeding points can be cauterized with bipolar cautery.

Transconjunctival Approach

The transconjunctival approach offers two treatment options: preseptal and postseptal. The postseptal approach is the most popular as well as the safest and easiest route to accessing the periorbital fat compartments. This approach only allows fat excision. The incision is made 4 to 5 mm below the tarsal border at the level of the vascular arcade. The conjunctiva and lid retractors are incised together, and the fat pockets are immediately identified and excised as needed.

Options for Lower Eyelid Rejuvenation

Components	Trans-conjunctival Preseptal	Trans-conjunctival Postseptal	Transconjunctival and Laser Resurfacing or Skin Pinch	Skin-Muscle	Skin-Muscle and Orbicularis Flap	Trans-palpebral Midface Lift
Skin	+	+	++	++++	++++	++++
Muscle	+	+	+	++++	++++	++++
Fat	++++	++++	++++	++++	++++	++++
Lid-cheek interface	++++	—	—	—	+++	++++

Degree of effectiveness indicated by the number of pluses.

The preseptal approach affords the opportunity to resect fat as well as the option to redrape the fat; it also provides access to the midface region. The incision is made along the tarsal border through the conjunctiva and lid retractors, then over the peri-orbital septum toward the orbital rim.

These transconjunctival approaches obviously will not allow excision of skin or muscle. Some have advocated approaching the fat and the midface through the transconjunctival approach and adding a simple skin-pinch excision to deal with the excess lower eyelid skin. Laser resurfacing with transconjunctival blepharoplasty is another option. The major advantage of the transconjunctival approach is the fact that no incisions are made in the orbicularis, thus minimizing, if not totally eliminating, the risk of lid retraction. I have found the transconjunctival approach for fat excision to be safe and effective with minimal if any risk of lid retraction. I have also found that it is much more difficult to manipulate fat and to access the midface through a pre-septal transconjunctival approach. I prefer to manipulate the fat and approach the midface through a transcutaneous muscle-skin flap. (See Chapter 33 for more detailed information on transconjunctival blepharoplasty.)

Transcutaneous Approach

The traditional transcutaneous skin-muscle flap is still my preferred approach to the lower eyelid in a patient who requires more than simple fat excision. This approach, especially any incision in the orbicularis, has come under considerable attack and scrutiny over the past few years. Some believe that any incision within the orbicularis will lead to its denervation and result in lid retraction. However, the cause of lid retraction is multifactorial, with orbicularis denervation merely one of the many potential causes.

Causes of Lid Retraction

- Anterior lamellar insufficiency
- Middle lamellar scarring
- Lid laxity
- High-risk patient
- Orbicularis muscle excision/denervation

The anterior lamella is composed of skin and the orbicularis muscle. Overresection of skin and muscle will lead to lid retraction. This is easily avoided through judicious skin excision. The middle lamella is composed of the periorbital septum and periorbital fat. Without doubt, scarring of the middle lamella is a major cause of lid retraction, and any procedure requiring manipulation within the middle lamella will increase the risk of lid retraction. This risk is minimized through meticulous dissection and hemostasis in the middle lamella and aggressive treatment of any postoperative bleeding or hematoma.

Unrecognized or untreated lid laxity is also a major cause of lid retraction. The routine application of lid-anchoring techniques in patients undergoing the transcutaneous skin-muscle flap approach and middle lamellar manipulations significantly reduces the risk of lid retraction. Horizontal lid shortening, if indicated, is also my routine. This is particularly appropriate for high-risk patients, including those with prominent or enophthalmic eyes and for anyone undergoing a secondary blepharoplasty. There is no question that true and complete denervation of the orbicularis, especially the pretarsal portion, will lead to lid retraction. Similarly, there is no question that a 5 mm rim of innervated orbicularis should remain on the tarsal plate.

The question of denervation is currently a topic of much debate. The orbicularis is innervated by the zygomatic and buccal branches of the facial nerve. The bulk of the orbicularis muscle, the extracanthal orbicularis, is innervated by the zygomatic branches; classically, these branches run from below upward almost perpendicular to the tarsal plate, and there is no question that division of the orbicularis as in the skin-muscle flap approach, will divide these branches. The extracanthal orbicularis is responsible for squeezing the eyelid, whereas the inner canthal orbicularis (that part of the orbicularis within 5 to 10 mm of the medial canthus) is responsible for eyelid closure, blinking, lower lid tone, and the tear pump.

MOTOR INNERVATION—PERIORBITAL REGION

This extracanthal portion of the muscle is innervated by the buccal branches and is usually preserved with the standard skin-muscle incision unless the incision in the muscle is continued all the way to the medial canthus. Leaving a 5 mm segment of pretarsal muscle on the tarsal plate and limiting the incision in the orbicularis to within 10 to 15 mm of the medial canthus will preserve a functioning, fully innervated portion of the orbicularis with adequate lid tone and closure.

I individualize the extent of the incision in the orbicularis muscle. I approach the lower eyelid through the skin incision and elevate a small skin flap; the orbicularis muscle is then divided separately and elevated as a combined skin-muscle flap. The extent of the incision I make in the orbicularis depends on my plans for the middle lamella.

If I do not plan any middle lamellar manipulations, such as fat excision or redraping, I make a *limited-access* incision in the orbicularis starting 10 mm lateral to the lateral canthus and extending up to 10 mm medial to the lateral canthus. This short incision allows access to the entire midface complex. It also enables release of the arcus marginalis all the way to the medial canthus, identification and preservation of the infraorbital nerve, and full subperiosteal dissection of the midface. I prefer to do the dissection with a headlight and a slim retractor, although others have advocated the use of the endoscope.

If fat redraping or dermis fat augmentation is planned, then the orbicularis incision is extended to within 10 to 15 mm of the medial canthus with a *full-access incision*. Both of these incisions allow me to excise as much skin as needed, elevate and fix the midface, redrape the orbicularis, and resect any orbicularis excess. Occasionally, in a patient who has excess periorbital fat, the limited-access incision may be combined with transconjunctival fat removal.

Orbicularis Flap

All of the transcutaneous skin–muscle flap procedures on the lower lid include orbicularis muscle flap redraping. This serves two purposes: functional and aesthetic. The orbicularis is redraped so that it sits snugly against the lower lid tarsus and adds extra support to the lower lid. Redraping with a vertical or combined diagonal and vertical vector will elevate the midface complex, especially the diagonal vector, and will further enhance the youthful appearance of the lower lid.

Transpalpebral Midface Lift

Many approaches are available to rejuvenate the midface area. I prefer this combined approach, because it allows the lower lid and midface to be treated as a single unit. I make a limited-access or full-access incision, depending on the need for middle lamella manipulation. Through either approach, a full subperiosteal dissection and elevation of the midface are performed. I include some subperiosteal dissection below the infraorbital rim on all blepharoplasties in type II, III, and IV patients.

Regional Procedures

Blepharoplasty is one component of periorbital rejuvenation. Often upper lid blepharoplasty is combined with some type of brow or forehead rejuvenation. The lower lid is so intimately involved with the midface complex that I think of the lower lid and cheek as one entity. Therefore, in almost all blepharoplasties for type II, III, and IV patients, I perform a midface lift; the extent, of course, is individualized, depending on the degree of aging and our goals for the patient. These regional procedures reflect the approach to facial rejuvenation, addressing facial zones or the entire face rather than individual components, such as the eyelids, brow, or midface.

Ancillary Procedures

The surgical procedures described will rejuvenate the upper and lower eyelids and improve the relationship of the upper lid and brow, and the lower lid–cheek junction and midface. Frequently, additional ancillary procedures are performed to enhance the result. These include peels, laser resurfacing, alloplastic implants, and fat grafting or fillers as an adjunct.

Laser resurfacing or peeling of sun-damaged, wrinkled skin at the time of blepharoplasty is a safe procedure, because the skin has been elevated as a reliable musculocutaneous flap with a full blood supply.

Fat is the filler material of choice around the eyelids and cheek. Although autologous fat injections are frequently the primary treatment for aging in the periorbital area, they also have a significant role as an adjunct to lower lid blepharoplasty and midface lift. As discussed previously, dermis fat is placed along the orbital rim to enhance the results in patients who have a deficiency in this area. Alloplastic materials, especially cheek implants, may also enhance the results.

Results

This woman in her midforties exhibited type II aging of the lower lid–cheek junction. She also had lid laxity, a round eye, and scleral show bilaterally. She underwent upper and lower lid blepharoplasties with a transpalpebral midface lift and lid anchoring to correct the lid laxity and scleral show. She also had a face and neck lift. Her postoperative result shows correction of the aging changes of the lower lid and correction of the lid laxity and round eye.

This middle-aged woman had type II aging of the lower lids, brow ptosis, grade IV glabellar and forehead lines, and grade III aging of the lower lid–cheek junction and nasolabial folds. She was treated with an endoscopic brow lift, upper and lower lid blepharoplasties with a transpalpebral midface lift, and erbium laser resurfacing of the forehead and glabella. Postoperative views show an improved brow position, lid–cheek junction, midface, and nasolabial folds. The split-face view more dramatically demonstrates the rejuvenative effect of these procedures.

This woman in her late forties had type II aging changes of the lower lids, midface, and jowls. She underwent a short-scar face lift, rhinoplasty, and lower lid blepharoplasty, with fat redistribution and orbicularis redraping. She was very pleased with the improvement in the lower lid-cheek junction, nasolabial folds, and perioral area.

This woman, who is in her sixties, had type III aging of the lower lids, as well as lid laxity, tear-trough deformity, nasojugal grooves, and early development of malar bags. Upper and lower lid blepharoplasties with a transpalpebral midface lift, orbicularis redraping, and canthopexy were performed. She also underwent concomi-

tant erbium laser resurfacing of the periorbital area. The postoperative result shows improvement in the lid-cheek junction, with amelioration of the malar mound and early festoons.

More severe aging changes are evident in this 60-year-old woman, who had type IV aging of the lower eyelids. She had lid laxity; the lateral canthus was significantly lower than the medial canthus. She also had malar mounds and festoons. To address these problems, she underwent lower lid blepharoplasty with a transpalpebral mid-face lift, horizontal lid shortening with cantholysis and canthoplasty, and a face and neck lift. Her postoperative result shows significant improvement in the lower lid-cheek junction, amelioration of the festoons, and improved eyelid position.

This 40-year-old woman had prominent eyes with a Hertel measurement of 23, thus making her a high-risk blepharoplasty patient. She underwent lower lid blepharoplasty with fat redistribution and placement of a primary spacer graft with AlloDerm and canthopexy and a short-scar face lift.

Release of the lower lid retractors is shown (*left*). The primary AlloDerm spacer is placed (*middle*), and the fat is redistributed (*right*).

This split-face view demonstrates the postoperative improvement in the lower lid–cheek junction, with normal lid position.

Long-Term Results

This type II patient is shown 9 years after an endoscopic brow lift, upper and lower blepharoplasty with fat redistribution, orbicularis redraping, and canthopexy.

Preoperative

3 months postoperatively

Another type II patient demonstrates a typical result; she is shown 3 months, 5 months, and 5 years after a skin–muscle flap blepharoplasty with fat redistribution, orbicularis redraping, and canthal anchoring.

5 months postoperatively

5 years postoperatively

Choosing the Best Option

OPTIONS FOR LOWER EYELID BLEPHAROPLASTY

CHAPTER 28

Upper Eyelid Blepharoplasty

MARK A. CODNER, JUAN DIEGO MEJIA

Blepharoplasty is one of the most commonly performed surgical procedures in the United States. Blepharoplasty in the upper lid is generally less surgically demanding than in the lower lid. However, serious complications such as lagophthalmos and corneal exposure can occur unless the surgeon uses sound judgment. The procedure must be safe, with conservative skin removal, while preserving function and ensuring upper lid closure. The amount of skin left behind in the upper lid is more important than the skin that is removed. Careful assessment of the eyebrow position is essential, because brow ptosis can be a substantial contributing factor to dermatochalasis. It is important to identify risk factors that could increase the potential for complications after blepharoplasty. Once assessment and planning are complete, the blepharoplasty procedure must be performed with precision to achieve the desired goal.

Evolution of Technique

One of the earliest reports of surgery of the eyelids was during the tenth century, when Avicenna (980-1037) noted that excess upper eyelid skin caused visual impairment. Techniques were developed to excise these folds to improve vision. In 1792, in the European literature, Beer first described the excess upper eyelid skin that is now known as *dermatochalasis*. The term *blepharoplasty* was used by Von Graefe in 1818; however, the term was actually applied to reconstructive procedures that were used to correct defects of the upper eyelid caused by excision of carcinoma. Although blepharoplasty was initially used to describe any reconstructive surgical procedure that corrected or shaped the eyelids, the term was later applied to cosmetic procedures, which were developed in the mid-nineteenth century. Descriptions of blepharoplasty techniques were published by a number of authors, including MacKenzie (1830), Alibert (1832), Graf (1836), and Dupuytren (1839), all of whom recommended skin excision only. The presence of pseudoherniation of orbital fat was first described by Sichel (1844), and Bourguet (1929) was the first to propose that fat be removed in addition to skin during blepharoplasty. Bourguet also described two separate fat compartments in the upper eyelid. He was reportedly the first to describe removal of lower eyelid fat through a transconjunctival approach. Joseph (1931) reported on surgical markings for upper and lower eyelid blepharoplasty incisions; these markings are still being used today. Castanares (1951) published one of the initial comprehensive reports of eyelid fat compartments of the upper and lower eyelid. Modern blepharoplasty techniques continued to evolve after World War II through the contributions of many excellent surgeons. Some of the notable surgeons who contributed to the evolution of blepharoplasty include Sheen (1974), who reported the technique of levator fixation for the creation of a supratarsal fold as well as excision of upper lid orbicularis oculi muscle in addition to skin excision, and Baker and Gordon (1977), who refined the technique of upper lid blepharoplasty.

Indications and Contraindications

Candidates for upper blepharoplasty are those with valid physical findings that are amenable to surgical improvement. Typical complaints include excess upper eyelid skin and upper eyelid folds. Candidates should demonstrate complete upper lid closure, as well as normal velocity of closure movement; this is necessary to provide adequate protection of the cornea, thereby preventing exposure. After a normal upper lid blepharoplasty, a small amount of lid closure velocity can occur. Patients who have normal precorneal tear film, ocular motility, Bell's phenomenon, and corneal sensation can usually tolerate this transient event.

Patients with certain preexisting conditions may be at risk of complications after blepharoplasty.

Blepharochalasis, or chronic puffy eyelids, is caused by repeated episodes of extreme eyelid edema, erythema, and thin excess skin resulting from a histamine response and is related to increased levels of immunoglobulin E. This rare condition also seems to be exacerbated during menstrual cycles. Unlike dermatochalasis (excess upper eyelid skin), it is difficult to correct and likely to recur.

Patients with rosacea are predisposed to corneal dryness and possible ulceration from exposure of the cornea after blepharoplasty. Patients with a known history of sarcoidosis should be considered at increased risk for healing complications. Non-caseating granuloma formation in blepharoplasty incisions has been reported; this occurs as a result of sarcoidosis of the surgical scar.

Pemphigus is an autoimmune disorder that leads to chronic inflammatory changes of the conjunctiva and ocular adnexa. Scar contracture of the conjunctival fornix may occur, causing foreshortening and lid malposition. Another periorbital disorder associated with increased risk of complications is benign essential blepharospasm, an involuntary disorder of spastic orbicularis oculi muscle, which often contributes to redundant upper eyelid skin. Blepharoplasty should be avoided, because improve-

ment in symptoms is unlikely. Current management includes a nonoperative approach that involves periorbital injection of the orbicularis oculi muscle with *botulinum* toxin.

Medical Conditions That Could Increase the Risk of Complications

- Blepharochalasis
- Rosacea
- Sarcoidosis
- Pemphigus
- Benign essential blepharospasm
- Graves' disease
- Dry-eye syndrome
- Menopause

Aesthetic Considerations

Concepts of beauty vary, and there are also significant differences among individuals in upper lid anatomy. When looking at different images of women considered beautiful, we see that beautiful eyelids can differ in regard to the amount of visible skin above the lashes, accentuation of the upper lid, and fullness of the area above the brow. The first step in planning upper lid blepharoplasty is to define specific aesthetic goals for each patient. Patients commonly have their own personal goals, and these should be defined and clarified before surgery. They usually desire a crease-fold relationship similar to their appearance in their youth. Dramatic changes caused by overresection of upper lid tissue can create a hollowed or operated appearance that may be unnatural for the patient.

In general, most women want a more visible eyeshadow space with a high upper lid crease and an arched brow. A lower crease, narrower eyeshadow space, and a flatter brow are the standards in men. Commonly, men need brow stabilization during surgery to avoid postoperative brow drop and narrowing of the brow-lash distance after upper lid blepharoplasty.

Pertinent Anatomy

Key landmarks and danger zones to consider when performing blepharoplasty are discussed in detail in Chapter 26.

The muscular anatomy of the periorbital region is shown. The orbicularis muscle is divided into three separate components: the orbital, preseptal, and pretarsal divisions.

The orbicularis muscle is innervated by branches of the facial nerve. Diffuse innervation is supplied by the frontal, zygomatic, and buccal branches. Recent electromyographic studies and cadaver dissections showed evidence of significant innervation of the medial orbicularis muscle of the upper and lower lid from the buccal branch.

Cross-sectional anatomy demonstrates the anterior and posterior lamella as well as the layers of muscle, fat, and ligaments that contribute to the periorbital contour.

Preoperative Assessment

Medical History and Evaluation

The first step in a thorough evaluation includes a history directed toward identification of specific medical conditions that can increase the risk of complications. These conditions include blepharochalasis, rosacea, pemphigus, Graves' disease, and benign essential blepharospasm. Blepharoplasty may be contraindicated in these individuals. If the surgeon decides to proceed with the surgery, the blepharoplasty should be conservative to minimize the risk of corneal dryness or lid malposition.

Patients with puffy eyelids are often seen by the plastic surgeon with undiagnosed hyperthyroid or euthyroid Graves' disease. Preoperative evaluation should take into account the results of laboratory testing, including free T4 levels, and an endocrine

consultation may be appropriate. Ocular manifestations of Graves' disease often include upper and lower lid retraction, increased orbital volume, exophthalmos, and puffy eyelids. Standard blepharoplasty techniques should be modified to correct lid position because of the increased risk of corneal exposure and keratitis.

Patients with an underlying history of dry eyes, which is often associated with intolerance to contact lenses, require preoperative tear film evaluation, including Schirmer's test. Schirmer's test is performed by anesthetizing the conjunctiva in the inferior lateral fornix with tetracaine eyedrops. The excess tear film is blotted with a cotton-tipped applicator, and a Schirmer's strip is placed in the lateral fornix while the patient maintains a forward gaze. Tear production is considered decreased when less than 10 mm of the Schirmer's strip is wet after 5 minutes.

The combination of decreased tear production with increased operative tear film loss from lagophthalmos after blepharoplasty may contribute to significant corneal exposure, including the potential for keratoconjunctivitis or corneal ulceration. Patients with a history of dry eyes who have an abnormal Bell's phenomenon on physical examination are at particular risk for corneal exposure. To minimize complications in this group of patients, blepharoplasty should be approached with caution and performed conservatively. In addition, patients who have had recent LASIK surgery for vision enhancement should not undergo blepharoplasty for at least 6 months to allow adequate corneal sensation to return and to give the corneal incision adequate time to heal, minimizing the risk of superinfection.

In addition to patients with underlying medical conditions, patients with unrealistic expectations may be at risk for dissatisfaction and should be identified before surgery. This group of patients is quite varied and most commonly includes younger patients who demonstrate minimal anatomic findings that are out of proportion to their complaints. Patients who have had previous surgery performed by another surgeon and who are inordinately upset despite minimal imperfections also require careful evaluation and possible psychiatric screening. These patients should be asked to demonstrate the precise nature of their concerns, along with preoperative photographs of their eye appearance. If a valid complaint cannot be substantiated by careful evaluation, surgery should be deferred.

Physical Examination

The physical examination of patients who present for blepharoplasty should proceed sequentially to ensure complete assessment of the periorbital anatomy. Visual acuity is tested with a Snellen eye chart. Bell's phenomenon should be documented. If a patient has dry eyes or a history of dry eyes, a Schirmer's test is performed, and referral to an ophthalmologist should be considered.

Upper Lid

The upper eyelids should be evaluated for excess skin (dermatochalasis), excess orbital fat, eyelid ptosis, levator function, prolapse of the lacrimal glands, excess retroorbicularis oculi fat (ROOF) or brow fat pads, prominent supraorbital rims, and floppy upper lid syndrome. Asymmetrical upper eyelid folds may be caused by upper lid ptosis, brow asymmetry, upper lid retraction, or asymmetrical amounts of excess tissue.

Blepharoptosis is the abnormally low position of the upper eyelid on normal gaze. It is important to differentiate simple dermatochalasis from upper lid ptosis to ensure optimal results. Clinical measures that should be taken are the position of the upper lid margin, the levator function and the lid crease height. The upper lid margins should be symmetrical and should not be lower than 2 mm from the superior corneoscleral limbus. Levator function is assessed by measuring the upper eyelid excursion from extreme downgaze to extreme upgaze and should be more than 10 mm. This should be measured by stabilizing the eyebrow to limit contribution from the compensating frontalis muscle. The normal upper lid crease is 7 to 10 mm above the lid margin and is usually higher in women than in men. In simple dermatochalasis these measurements are normal. The type of blepharoptosis most commonly seen in an aesthetic patient is involutional ptosis, which may be seen in conjunction with dermatochalasis or brow ptosis. In this type, the patient will notice gradual descent of the upper eyelid, an elevated lid crease height, and normal levator function. These patients' ptosis can easily be corrected with tarslevator advancement during the upper blepharoplasty procedure.

Common Causes of Upper Lid Ptosis

- Congenital ptosis
- Involutional ptosis
- Aponeurotic dehiscence
- Myogenic ptosis—myasthenia gravis
- Chronic progressive external ophthalmoplegia
- Neurogenic ptosis—Horner's syndrome
- Mechanical ptosis—tumor, trauma

Patients who are thought to have upper lid ptosis should also be carefully evaluated for a history of congenital ptosis; aponeurotic dehiscence; myogenic ptosis, including myasthenia gravis; chronic progressive external ophthalmoplegia; neurogenic ptosis, including Horner's syndrome; and mechanical ptosis from tumor or trauma.

Patients with minimal unilateral acquired ptosis should undergo the cover test, which is performed by placing an eye patch over the ptotic eyelid for 5 minutes, after which the contralateral eyelid is evaluated. This often reveals an underlying ptosis in the contralateral eyelid, since there is decreased visual input from the ptotic eye. Hering's law of equal innervation states that decreased visual input from one eye with ptosis will result in increased and equal neural output to both eyelids to raise the level of the eyelids, resulting in an equal increase in activity of both levator muscles. The cover test is required to isolate and objectively evaluate the contralateral non-ptotic eyelid.

Preoperative evaluation also includes examination of the superior lateral orbit for prolapse of the lacrimal gland. Excess ROOF requires conservative removal of the brow fat pad lateral to the supraorbital nerve. This may be combined with an internal browpexy of the lateral brow. Extreme fullness of the superolateral orbital rim may be addressed with an osteoplasty using a burr to reduce the bony prominence.

The upper eyelid should be evaluated for floppy eyelid syndrome, which is common in large, burly men. The upper eyelid everts during forced closure; correction requires resection of a portion of the lateral tarsal plate with canthoplasty of the upper lid. Failure to correct this can result in postblepharoplasty closure problems: an overriding upper eyelid, chemosis, or separation from the globe.

Brow

The eyelid must always be considered in conjunction with the eyebrow. The eyebrow should be evaluated for ptosis and symmetry in addition to the aesthetic relationship between the height of the nasal and lateral portions of the brow. In men, the brow should be at the superior orbital rim, whereas in women, the brow should be above the rim, with the arch apex in line with the lateral limbus. Signs of brow ptosis include lateral upper eyelid hooding and a narrowed brow-lash distance. The descent of eyebrow fat and the excess upper lid skin that develops with age may obstruct vision. Compensation by frontalis contraction keeps the eyebrow above the orbital rim, clearing the visual field. Once the upper lid skin is removed, frontalis compensation is no longer necessary, and underlying brow ptosis becomes apparent. Concomitant brow lift or internal brow fixation through the blepharoplasty incision can help to stabilize the eyebrow in the proper position. Lack of brow stability will predispose the patient to descent of the brow after an upper blepharoplasty if the brow laxity is not corrected. Furthermore, patients with underlying unilateral upper lid ptosis may present with eyebrow asymmetry, which is apparent to the patient, even though the ptosis may not be.

Dynamic lines caused by activity of the procerus and corrugator muscles require evaluation and may be treated either nonsurgically with neurotoxin injection or surgically with a brow lift using an endoscopic approach, open approach, or transpalpebral corrugator resection combined with internal browpexy.

Patient Preparation

Preoperative instructions to the patient should include cessation of all medications that increase the risk of bruising and swelling, including aspirin, ibuprofen, and vitamin E. Homeopathic herbs such as *Arnica montana* and bromelain may reduce postoperative edema and ecchymosis, and we have used these routinely for more than 15 years. Patients should be instructed to carefully remove all makeup, particularly mascara residue, and to wash the face the morning of surgery. Blepharoplasty can be performed with the patient under general anesthesia or with intravenous conscious sedation. Patients should be placed in a reverse Trendelenburg position to decrease venous pressure. Surgical preparation includes application of a dilute solution of povidone-iodine to the eyelids and face, carefully avoiding exposure of the conjunctiva, and irrigation of the eyes with balanced saline solution before placement of corneal protectors.

Operative Technique

Anesthesia

After adequate intravenous or general anesthesia is obtained, we recommend administration of preoperative antibiotic agents. Local anesthetic consisting of lidocaine 1% with epinephrine 1:100,000 is injected with a 27-gauge needle into the planned area of resection of the upper eyelid. To reduce the risk of eyelid or retrobulbar hematoma, the marginal arcades and the deep orbital structures are carefully avoided. The infiltrate should be allowed to sit for 7 minutes before the incision to allow maximal vasoconstriction.

Markings

The patient's eyelids are marked on the operating table after induction of anesthesia. This permits more precise measurements using loupe magnification and calipers to ensure symmetry of markings on both eyelids. Fine, wooden-tipped applicators are used to mark the incisions with methylene blue.

It is possible to determine the amount of skin to be excised by using a forceps to pinch the excess skin and muscle. However, it is not our practice to premark the amount of skin to be removed by bunching. Functionally, the amount of skin that is to be removed from the upper lid is not as important as the amount of skin that is left behind after blepharoplasty. Four points, A through D, are important for the upper blepharoplasty markings.

The inferior excision line is drawn first. The initial mark indicates the upper eyelid crease at the level of the midpupillary line (point A). In women this is usually 10 mm above the lash margin and in men 7 mm above the lash margin. The markings are tapered inferiorly at the medial and lateral lid margins following the gentle curve of the upper lid crease. The lateral and medial marking should be 6 mm above the lash line superior to the respective canthi (points B and C). The medial aspect of the markings should not extend nasal to the caruncle to avoid webbing or epicanthal folds

above the medial canthus. The lateral extension should proceed in a crow's-feet skin line corresponding to the amount of redundant skin but should not extend past the lateral orbital rim to prevent a prominent scar.

The superior marking of the skin incision is started at the level of the lateral limbus (point *D*). At this point at least 10 mm of skin should be preserved between the superior incision and the beginning of the thick eyebrow skin. The superior mark is completed by following a gentle curve paralleling the contour of the lower marking and tapering nasally to reduce the amount of skin and muscle that is removed along the nasal half of the incision. No more than 5 mm of skin should be removed nasally; overresection of skin and muscle is poorly tolerated nasally and often results in lagophthalmos, which can cause corneal dryness. Because the cornea is much more forgiving of lagophthalmos in the temporal half of the upper lid, more aggressive skin removal can be performed laterally. Postoperative lagophthalmos in the nasal half of the upper lid causes more symptoms of corneal exposure. Therefore efforts to correct skin laxity in the nasal upper lid should be more conservative, relying on brow repositioning if possible.

The skin-pinch technique for skin removal is used only in patients who need a touchup after a previous blepharoplasty and in some primary patients who already have a well-defined eyeshadow space and upper lid crease but have small redundant skin folds.

During the process of marking, the surgeon should pay special attention to the presence of asymmetry of the eyebrow and eyelid fold. If the brows are asymmetrical preoperatively, the upper eyelid markings should closely approximate one another, but a concurrent procedure should be planned to correct brow position. However, if the lid folds are asymmetrical, symmetry can be achieved by removing different amounts of skin and muscle from each eyelid.

The complete upper eyelid marking is incised with a scalpel through the skin and orbicularis oculi muscle. The upper edge of the incision is completed with needle-tipped cautery, exposing the orbital septum.

The orbital septum is opened with Westcott scissors. This technique provides an *open-sky* approach to the preaponeurotic space and exposes the orbital fat. The septum should be opened along the upper incision to avoid injury to the aponeurosis, which is present posterior to the orbicularis muscle at the lower incision in the lid crease.

Removal of fat from the central and nasal compartment can be performed conservatively, carefully preserving the interpad septum between the central and nasal fat pads.

Overresection of fat in this area will result in an A-frame or peaked-arch deformity of the supratarsal crease. Preservation of fat at the interpad septum will maintain a symmetrical, gentle arch below the new upper lid fold. When fat excision is indicated, it can be performed by direct sculpting with the needle-tipped cautery, which allows greater precision and visualization of the medial palpebral artery. Clamping, resecting, and cauterizing fat should be discouraged, because this can result in uncontrolled bleeding. Inadequate cauterization can result in bleeding from the nasal fat pad. Poor visualization and indiscriminate cauterization within the deep nasal orbit have been reported to contribute to injury to the trochlea and superior oblique muscle. Patients with injury to the superior oblique muscle will exhibit diplopia and head tilt toward the side of the superior oblique injury after blepharoplasty. Preservation of fat should be considered to prevent creation of a hollow, more aged-appearing orbit.

Excess skin, muscle, and septum are resected with scissors beveling away from the levator insertion into the upper lid crease. This open-sky technique takes the same amount of septum and orbicularis as it does skin, which reduces the risk of postoperative lagophthalmos by reducing subcutaneous bulk. If the edges of a large skin resection are closed over large amounts of underlying orbicularis, a relative skin shortage is produced, causing upper lid tightness and decreased lid closure velocity.

Surgical disinsertion of the levator aponeurosis after upper blepharoplasty is a well-recognized cause of postoperative acquired ptosis. To minimize the potential for this, supratarsal fixation of the pretarsal skin muscle to the levator aponeurosis is performed as a routine part of upper blepharoplasty using a horizontal mattress suture of 6-0 Vicryl at the midpupillary line.

Lateral brow fullness is caused by a prominent bony orbital rim or by excessive brow fat (ROOF). The ROOF should be evaluated, and conservative resection of the brow fat pad can then be performed by retracting the upper lid edge of the blepharoplasty flap, exposing the superior orbital rim and ROOF. The redundant brow fat is marked and resected away from the orbital rim with electrocautery. The underlying periosteum should be left intact to prevent the development of restrictive adhesions.

Ptosis of the orbital lobe of the lacrimal gland may be present and should be corrected with suspension of the lacrimal gland into the lacrimal sac fossa. This is performed by placing the lateral horn on traction and suturing the levator aponeurosis to the arcus marginalis with a 6-0 Vicryl suture just at the level of the lacrimal gland to prevent future lacrimal gland ptosis. The levator aponeurosis needs to be placed on a downward stretch to eliminate the risk of postoperative lagophthalmos. To avoid postoperative dry-eye syndrome, the lacrimal gland should not be resected.

Internal brow fixation through the upper blepharoplasty incision can be performed in patients who have mild laxity and require lateral brow support. After upper blepharoplasty is completed, the superior lateral orbital rim and lateral brow area are exposed by retracting the superior blepharoplasty incision. The orbicularis and ROOF are dissected just superficial to the periosteum along the lateral third of the eyebrow.

The dissection continues upward and laterally for 2 to 3 cm. Dissection cephalic to the orbital rim should be performed bluntly with a cotton-tipped applicator to avoid injury to the perforating zygomaticotemporal vein found in this area. Care should be taken to completely release the lateral zone of fixation at the junction of the temporal line of fusion and supraorbital rim. An internal browpexy is performed using a 4-0 Prolene suture just deep to the dermis at the level of the inferior hair-bearing brow and the underlying periosteum. The brow can be sutured 5 to 10 mm above the orbital rim at the level of the lateral corneoscleral limbus to recreate the peak of the brow. Only mild elevation can be obtained with an internal browpexy, but it provides stabilization of the tail of the brow to prevent brow ptosis after the blepharoplasty, which results in residual skin folds laterally.

After removal of excess skin, muscle, and fat, the upper lid incision is generously irrigated with normal saline solution to remove any residual liquefied fat that can result in postoperative granuloma formation. The incision is closed with initial sutures placed superior to the lateral canthus with interrupted 6-0 nylon that align the skin and muscle. The incision lateral to the canthus is closed with interrupted 6-0 nylon sutures and the incision medial to the lateral canthus with a running 6-0 nylon. Although an intracuticular closure is commonly used, a running suture that encompasses both skin and muscle reduces tension on the dermis and leaves a better scar. In addition, the interposed muscle prevents formation of adhesions from the dermis to the aponeurosis, thereby minimizing contour irregularity and lagophthalmos.

Ancillary Techniques for Upper Lid Rejuvenation

Transblepharoplasty Excision of Corrugator and Procerus Muscles

The upper eyelid, by providing limited access to the forehead, may be thought of as a gateway to the medial and lateral brow. This gateway is limited by the supraorbital and supratrochlear nerves. Modification of the glabellar muscles through the

upper eyelid incision is effective in improving glabellar lines with minimal medial brow elevation. The ideal candidates for this procedure are patients who are undergoing an upper blepharoplasty, have glabellar frown lines, minimal or no brow ptosis, and no excess skin above the nasal radix.

After the upper lid blepharoplasty has been completed, the assistant retracts the superior blepharoplasty incision, helping to expose the glabellar area. Dissection is performed deep to the orbicularis toward the corrugator muscles with spreading scissors or a cutting needle Bovie. As the superior orbital rim is approached, one can identify the diagonal muscle fibers of the corrugator. Care should be taken to identify and preserve the supraorbital and supratrochlear nerve branches, which are visible at this stage. The supraorbital nerve is the larger and more lateral, and the supratrochlear branches are smaller, medial, and usually intertwined with the corrugator muscle.

Once the corrugator is identified, a small mosquito clamp is used to dissect it and bring it forward.

With the muscle isolated, coagulating current is used to resect a segment of the corrugator muscle, producing a central gap. Injuries to the trochlea or superior oblique muscle tendon are rare and are easily avoided by limiting any dissection behind the origin of the corrugator.

The procerus muscle can also be divided through the upper blepharoplasty incision. Patients with transverse glabellar or dorsal nasal skin lines from procerus muscle activity benefit from this procedure. The orbicularis is elevated, and then a pair of scissors are pushed blindly toward the nasal radix, cutting the fibers under the skin.

Postoperative swelling after these procedures is more prolonged than with standard blepharoplasty. Head elevation and ice packs help with the swelling. The use of diuretics and a short course of methylprednisolone (Medrol Dosepak) can be considered in some patients.

Postoperative Care

The patient's head should remain elevated to reduce edema and ophthalmic pressure. Ice packs or cold compresses are applied to the eyelids for 48 hours. The eyes should remain lubricated at all times with saline drops during the day and lubricating ointment at night. Lagophthalmos can be caused by periorbital edema; it resolves spontaneously in 1 to 2 weeks. In these cases the eyedrops and ointment are essential to prevent corneal exposure and abrasions. Before discharge the patient's vision should be evaluated and documented. Any signs of corneal irritation or decreased visual acuity require careful ophthalmologic evaluation including slit-lamp examination with the use of fluorescein eyedrops to evaluate the cornea. Patients are asked to avoid the use of eyelid makeup on the suture lines and contact lenses for 2 weeks after blepharoplasty. The sutures are removed 5 days postoperatively.

Complications

Vision Loss

Permanent vision loss is the most feared complication after blepharoplasty. If this occurs, it is usually caused by retrobulbar hemorrhage. In an epidemiologic study of more than 250,000 blepharoplasties, the incidence of retrobulbar hemorrhage was 1 in 2000, with a 1 in 10,000 risk of permanent visual loss associated with it. Acute retrobulbar hemorrhage may compress neurovascular structures, leading to ischemia of the retina, central artery, and optic nerve. Most hemorrhages occur within the first 24 hours after surgery (96%), and of these, more than half occur within the first 6 hours postoperatively. The patient can present with severe pain and pressure and visual changes that include hemianopsia, scotomas, or amaurosis fugax. Physical examination will reveal a tense and proptotic eye and loss of pupillary reflexes with diminished or absent extraocular movements. Urgent treatment should be implemented, because 90 to 120 minutes of ischemia can lead to irreversible blindness. An ophthalmic consultation should be obtained immediately. If intraocular pressure is elevated, topical and systemic glaucoma medications such as mannitol and acetazolamide (Diamox) are started. Systemic corticosteroids are needed to address significant edema. The patient should be taken back to the operating room. The sutures are removed and the surgical wound is reexplored to check for bleeding. If the condition remains unresponsive, lateral canthotomy and cantholysis are performed to relieve pressure. If these measures fail, a CT scan without contrast is warranted to rule out a posterior hematoma. In these cases bony decompression may relieve orbital apex compression. The algorithm on p. 884 outlines the means for assessing and treating retrobulbar hematomas.

Steps to Reduce the Risk of Retrobulbar Hemorrhage

- Maintain normal blood pressure.
- Inject anesthetic with care.
- Manipulate orbital fat gently during dissection.
- Ensure meticulous hemostasis.
- Place the patient in a head-up position postoperatively.
- Provide pain control measures.
- Instruct the patient to avoid strenuous activity.

Vision loss from perforation of the globe during the blepharoplasty can be prevented with the use of corneal protectors. Diplopia may result from impaired ocular motility. In upper lid surgery it can be from edema or stretching of the vertical recti and superior oblique muscles. Conservative management is recommended since the diplopia will often resolve in the first few months as the edema and inflammation subside.

Hematoma

When a hematoma is seen intraoperatively, the wound should be explored, evacuation performed, and proper hemostasis obtained. Small superficial postoperative hematomas are treated conservatively with ice compresses and rarely need to be drained by reopening the wound. If they persist, they can be evacuated with needle aspiration or stab wound drainage after spontaneous clot dissolution 7 to 10 days later. Large, expanding hematomas seen after surgery require immediate surgical exploration and evacuation. Residual areas of organized clotting can result in nodular irregularities or scarring of the middle lamella.

Lagophthalmos

Lagophthalmos may result from excessive skin resection or edema. It can lead to patient discomfort from exposed keratopathy and is worse in those with a preexisting dry-eye condition. Lagophthalmos after blepharoplasty is usually temporary and can be managed conservatively with patient reassurance, light massage, taping, and application of lubricants day and night. If conservative therapy fails, surgical options include skin grafting, and release of orbital-septal adhesions. When placing a full-thickness skin graft in the upper lid, it must not distort the upper lid crease. It is placed in the pretarsal area not extending above the crease (over the eyeshadow space).

Dry-Eye Syndrome

Dry-eye syndrome is not an uncommon sequela after blepharoplasty. Even minimal widening of the palpebral fissure with blepharoplasty can produce keratopathy in patients with low tear production. Patients in their fifties or sixties (when tear production is diminished), women receiving estrogen replacement therapy, patients who cannot tolerate contact lenses, or those with a history of increased sensitivity and dry-eye irritation are especially at risk for dry-eye syndrome. Performing Schirmer's test is important in the preoperative evaluation of these patients. Patients with a significant decrease of tear production with an absent Bell's phenomenon are not suitable candidates for aesthetic blepharoplasty. Initial treatment consists of ocular lubrication with artificial tears and ophthalmic ointment. Failure of this treatment should prompt ophthalmologic examination and consideration of punctal occlusion or additional antiinflammatory eyedrops such as topical cyclosporine.

Blepharoptosis

Eyelid ptosis can be a common finding several hours after the procedure as a result of the effects of local anesthesia on the levator muscle. Persistent ptosis can be caused by edema or injury to the levator. Mild cases may resolve spontaneously and can be managed expectantly for at least 3 months before surgery is considered. Severe ptosis with poor levator function requires reexploration and levator repair. If injury to the levator is noticed at the time of surgery, it should be sutured back to the tarsus.

Overresection of Fat

Conservative blepharoplasty is the rule today, since overzealous fat resection can lead to an unaesthetic, hollow, skeletonized appearance. Options for correction of a sunken upper lid include fat transposition or grafting and the use of synthetic fillers.

Infection

Infection is very rare after blepharoplasty because it is a highly vascularized area. If infection occurs, it can be treated with antibiotics and drainage if necessary.

Results

The following cases have been selected to represent a variety and continuum of patients who demonstrate age-related changes of the eyelids and periorbital region.

Patients with a heavy upper eyelid fold who did not have a visible significant pre-tarsal space, even in youth, should undergo conservative resection to avoid a change in the shape of the upper eyelid by creating a deep upper lid sulcus.

In men, removal of skin and muscle from the upper eyelid should be conservative to preserve a low crease and avoid feminization of the upper eyelid.

Floppy upper eyelid syndrome is common in large, burly men. This patient underwent upper and lower blepharoplasties with canthoplasty of the upper and lower eyelids.

This patient had brow asymmetry and ptosis on the left side, with compensatory frontalis activity. He is shown 6 months after bilateral upper and lower blepharoplasties and an endoscopic brow lift.

Concluding Thoughts

The upper lid and brow region is a very important determinant of facial aesthetics and plays a vital role in facial rejuvenation. Although upper blepharoplasty is less complex than lower blepharoplasty, judicious preoperative assessment and operative technique are essential to avoid possible complications such as lagophthalmos, A-frame deformity, a shrunk-lid appearance, or eyelid ptosis. High-risk patients have a lower tolerance to the anatomic and biomechanical changes that follow a blepharoplasty; such individuals must be identified before the procedure. The technique described in this chapter represents the basic approach to upper lid blepharoplasty. The surgical outcomes have been carefully evaluated and are associated with a low rate of complications and a high rate of patient satisfaction. The key principles for upper blepharoplasty include conservative removal of skin, muscle, and fat to avoid a hollow upper lid sulcus or postoperative lagophthalmos. Adherence to these basic principles significantly contributes to achieving the overall goal, which is excellence in blepharoplasty results.

Clinical Caveats

Upper lid blepharoplasty, although technically less challenging than lower lid blepharoplasty, requires familiarity with periorbital anatomy.

Individual goals in upper lid blepharoplasty vary and must be determined on an individual basis.

Upper lid functionality is more important than aesthetics and should always be maintained after upper lid blepharoplasty.

High-risk patients can be recognized preoperatively with systematic clinical evaluation.

Avoid placing the upper blepharoplasty incision more than 8 to 10 mm above the lid margin.

Fat preservation and conservative resection of skin and muscle during upper blepharoplasty should be performed to reduce the appearance of a hollow orbit.

The amount of skin that is left behind in the upper lid is more important than the skin that is removed.

Supratarsal fixation of the pretarsal skin and muscle to the levator aponeurosis should be a routine part of upper blepharoplasty to minimize the development of postblepharoplasty ptosis.

Procedures like eyelid ptosis correction, lacrimal gland suspension, lateral brow-pexy, and corrugator and procerus excision can be performed through the upper blepharoplasty incision.

Annotated Bibliography

Carraway JH, Miller JR, Lewis BK. Reoperative blepharoplasty. In Grotting JC, ed. Reoperative Aesthetic & Reconstructive Plastic Surgery. St Louis: Quality Medical Publishing, 2007.

This chapter focuses on the most common and the most devastating complications after upper lid blepharoplasty.

McCord CD, Codner MA, Nahai F. Upper lid blepharoplasty. In McCord CD Jr, Codner MA, eds. Eyelid and Periorbital Surgery. St Louis: Quality Medical Publishing, 2008.

This chapter is a thorough updated review on upper eyelid blepharoplasty. It discusses aesthetic considerations, preoperative evaluation, and operative technique. Ancillary procedures that are sometimes performed with upper blepharoplasty like transblepharoplasty excision of corrugator and procerus muscles are also discussed.

CHAPTER 29

Upper Blepharoplasty in the Asian Patient

WILLIAM P. CHEN

Double eyelid surgery refers to the aesthetic procedure of creating an upper eyelid crease in an Asian patient who does not have a crease. It has evolved over the last century from using buried suture ligatures into a more anatomically based form of cosmetic blepharoplasty. In Asian countries, it is one of the most frequently performed aesthetic surgeries. I coined the term *Asian blepharoplasty* in 1987 while attempting to define the skills and pitfalls necessary for performing primary and revisional surgery in Asians.

The suture ligation methods are thought to be less invasive and easier to learn, but they require tremendous practice to be adept. The external incision methods are easier to adapt by surgeons who have been exposed to the usual training in blepharoplasty. I think that the suture ligation method yields a relatively static crease, whereas the incisional approach with crease construction yields a more dynamic crease that mimics a natural crease on upgaze and downgaze.

In this chapter I will concentrate on the external incision method, because it yields more predictable results.

Indications and Contraindications

Bearing in mind that Asian blepharoplasty is a form of aesthetic surgery, suitable candidates include individuals who believe that adding a natural-appearing crease to their eyelid fissure will enhance the shape and proportion of their eyelids. This should certainly be performed within the anatomic parameters appropriate to Asians and appropriate to the individual's facial dimensions. Contraindications are the same as those which apply to any prospective blepharoplasty patients, including individuals who have unrealistic expectations of the changes that such a procedure can produce. Those who may not psychologically tolerate the significant change in look of the eyelid fissure should not undergo such an aesthetic alteration. A patient must be 16 years of age or older before I perform this operation, since there is still a very slight probability that a crease may be secondarily acquired around this age.

Anatomy of the Asian Eyelid, Incidence of the Crease, and Crease Shape

On average within a family, there is approximately a 50% prevalence of an upper eyelid crease, and this seems to generalize to Asian populations who are of Han background (Chinese, Koreans, and Japanese). There are geographic variations in incidence of the crease, ranging from 25% to 80% or more, but the overall incidence

of 50% seems to hold true in my clinical experience. The vertical height of the upper tarsus is typically between 6.5 and 7.5 mm, and on rare occasions 8.0 to 8.5 mm. This is in contrast to the average dimension in non-Asians of 9.0 to 10.5 mm vertical height.

The current consensus on the distinguishing features of a creased upper eyelid versus one without a crease in Asians seems to be the presence or absence of terminal interdigitations of levator aponeurotic fibers into the pretarsal orbicularis oculi fibers and intermuscular septa, located in an area just slightly below or along the superior tarsal border. The images above show an Asian upper eyelid in an open position without any crease indentation (*left*) and with the presence of a crease (*right*).

Asians who have a natural crease tend to manifest either a nasally tapered crease (*left*) or a parallel crease (*right*). The nasally tapered crease is low-set and runs parallel across the ciliary margin over the central and lateral portion of the upper lid, while over the medial portion it converges inward toward the medial canthus, often blending into a small ethnic medial canthal fold. The parallel crease runs parallel across the ciliary border; over the medial portion, it simply runs independent of and above any residual medial canthal fold.

Both these crease shapes are different from the semilunar crease typically seen in non-Asians. The non-Asian upper eyelid typically shows a semilunar crease line on the skin on downgaze, although this may manifest with either a parallel shape or semilunar shape when viewed straight on.

Preoperative Assessment

It is common to see patients with asymmetry of the two upper lids as well as its crease, asymmetry of fat and soft tissues (skin and orbicularis oculi muscle), asymmetry in shape and height, and possibly latent ptosis.

A detailed history should be taken, outlining the goals of the procedure from the patient's viewpoint, and an eye examination is done to document the various factors mentioned previously. I note the shape of the face, its size, the position of the brow, and its separation from the upper lid margin. These observations are combined into a recommendation for the patient.

A surgically constructed crease that does not fold in well can result from borderline levator contractility with no true anatomic ptosis. Patients are shown representative before-and-after photos and photos of patients in various stages of the healing process so their expectations will be realistic. Photos are taken in primary as well as revisional cases.

Preoperative Planning and Anesthesia

Preoperative sedation and anesthetic include a combination of 10 mg of diazepam (Valium) and 1 tablet of hydrocodone/acetaminophen (Vicodin) (or 1000 mg of acetaminophen) given orally an hour before the procedure. The local anesthetic is 2% lidocaine with a 1:100,000 dilution of epinephrine. A 30-gauge needle is used, and the volume injected is seldom more than 1 ml for each upper eyelid. A controlled flow of room air is supplied through a nasal cannula. An intravenous line is inserted in case further sedation is necessary.

Operative Technique

The surgical steps are as follows:

1. Marking the desired eyelid crease
2. Skin incision
3. Transection through the orbicularis oculi along the upper edge of the skin incision
4. Approaching and opening the orbital septum
5. Handling the fat pads
6. Excision and debulking of the preaponeurotic platform
7. Resetting of tissue planes
8. Anastomosis of the levator aponeurosis to the skin: lid crease sutures and wound closure

29-1 Upper
blepharoplasty in
the Asian patient

Marking the Desired Eyelid Crease

Marking involves precise measurement of the vertical height of the central portion of the everted upper eyelid tarsus. This image shows the measurement of central height of the tarsal plate on the right upper lid with a corneal protector in place. Typically the central tarsal height is between 6.5 and 7.5 mm, with an occasional patient manifesting 8.0 to 8.5 mm. The crease height is determined; typically 7 mm is chosen based on patients' stated preference during their initial consultations. A higher or lower crease will be no more than 0.5 mm on either side of this average. This central crease height is marked on the skin side and will determine the overall height of the crease, whether one is planning a nasally tapered crease or a parallel crease. The nasally tapered crease is chosen in more than two thirds of my patients and is easier to mark and execute in my hands. The crease shape is simply merged toward the medial canthus when approaching nasally. For a parallel crease shape design, the surgeon should try to stay parallel to the lash line while approaching the medial canthus. A segment of redundant skin and soft tissue is included in the line of excision—typically a strip of skin measuring about 2 mm centrally, 2.5 mm laterally, and 1 mm medially. Most of the tissue swelling from the local anesthetic's infiltration should have subsided by this point of the initial marking.

Skin Incision

The skin is incised with a No. 15 surgical blade along the upper and lower lines of marked skin. The photo shows the subcutaneous incisions made along the upper and lower lines of skin marking. A dry 4 × 4 dressing is used to stabilize the skin layer during this step. The blade tip cuts through the skin full thickness and stops just when the fascial tissue overlying the orbicularis oculi is reached. The entire length of the incision often requires several positioning and repositioning steps; this demands utmost precision.

Transection Through the Orbicularis Oculi Along the Upper Edge of the Skin Incision

I use a Colorado tip needle on a monopolar cautery (Bovie) with a low setting on the cutting mode to make the transection through the orbicularis oculi muscle. The tip is intentionally beveled upward along the orbicularis so that the orbital septum is reached along a higher level than that of the superior tarsal border. Once transection through the preseptal orbicularis oculi has been completed, as shown above for the right upper lid, a portion of the orbital septum is open and the preaponeurotic fat pads can be seen. With this maneuver, the cautery tip is likely to reach the preaponeurotic (postseptal) fat pad rather than injure the levator aponeurosis, and it allows identification of the preaponeurotic space. This step of beveled transection

through the preseptal orbicularis oculi constitutes my *first vector*. The orbicularis typically is the most vascular layer, and it is worthwhile to be meticulous in controlling any bleeding here with bipolar cautery.

Approaching and Opening the Orbital Septum

Preseptal fat is often seen commixed with orbicularis fibers plus fascial tissues and can misdirect the surgeon into thinking that it is the deeper preaponeurotic fat, which is distinctly globular, fluctuant, and easily prolapses through small rents in the orbital septum as one reaches it. The septum is opened horizontally with blunt spring scissors; the surgeon must make certain to slant the septal cut upward to avoid cutting blood vessels in the fat pads, not slanting downward toward vessels of the aponeurosis or the aponeurosis itself. As shown, after the septum is opened, the preaponeurotic space and levator aponeurosis can easily be seen.

Handling the Fat Pads

Partial excision of the preaponeurotic fat pad

After the septum is opened horizontally, the fragment of tissues bounded by the upper skin incision and transorbicularis *first vector* can be rotated away from the underlying levator to form a myocutaneous strip. A tissue retractor is applied on the myocutaneous strip to explore the preaponeurotic space. Within the space one may observe fluctuant preaponeurotic fat, or amorphous, bound-down fatty strands, or

smaller “islands” of fat. Depending on the preoperative evaluation of the sulcus and the brow relationship to the upper lid margin, the surgeon may choose to do one of the following:

1. Reposition all preaponeurotic fat.
2. Partially excise some preaponeurotic fat along the superior tarsal border, creating a clearance along the preaponeurotic platform.
3. When fat strands or islets of fat are observed, dissect this off and allow it to retract upward to fill in the sulcus. This maneuver appears to greatly facilitate the glide mechanism (glide plane) of the levator relative to the anterior skin lamella, allowing an eyelid crease to indent dynamically against a passively relaxed preseptal skin-muscle layer (the eyelid fold).

Excision and Debulking the Preaponeurotic Platform

The myocutaneous strip of tissue redundancy (2 mm of skin plus a slightly larger fragment of preseptal orbicularis oculi just above the upper tarsus) can be excised along the superior tarsal border using a Bovie cautery tip. This transection through the lower edge of the orbicularis strip is called the *second vector* and completes the trapezoidal debulking of the preaponeurotic platform. If there is some residual fullness along the lower edge of the skin incision, I may trim off some inferior orbicularis fibers so that it will be less likely to interfere with the crease construction. The excision of an orbicularis strip along the inferior edge of the pretarsal skin is shown above.

In summary, with skin incision and only two additional steps (the first vector through the orbicularis and septum; the second vector through the orbicularis), one can complete a beveled excision of these layers—skin and orbicularis oculi as a trapezoidal fragment, and a fragment of orbital septum overlying the distal 4 to 5 mm of the levator aponeurosis. Bleeding is controlled along the two planes that involved transection through the vascular orbicularis.

Resetting the Tissue Plane

Resetting the tissue plane is an important step in primary as well as revisional Asian blepharoplasty. After the redundant skin and muscle have been appropriately trimmed and the preaponeurotic fat reduced or repositioned, it is essential to reset the tissue planes by properly positioning the anterior skin-muscle layer in relation to the underlying aponeurosis. The surgical drapes are loosened to facilitate this resetting. This maneuver avoids creating lagophthalmos or secondary ptosis. The original operative field may have been isolated using surgical drapes, towels, and adhesive drapes; therefore the surgeon may inadvertently attach the skin edges at a higher point along the aponeurosis rather than just along the superior tarsal border. This results in an overly high crease and secondary ptosis; the frontalis muscles then become overactive, and the eyebrows are unnaturally arched. In revisional cases, this resetting allows some skin recruitment and brings in additional soft tissues to partially fill in any prominent sulcus from fat excision associated with previous aggressive blepharoplasty.

Wound Closure and Crease Construction

The crease shape and height is controlled through accurate design as well as meticulous application of crease-forming sutures; I prefer the soft texture of 6-0 silk sutures for this purpose. They are applied from the lower skin edge, through the aponeurosis along the superior tarsal border, through the upper skin edge, and then are tied down, as shown above. Six to nine interrupted sutures are typically used. The rest of the wound can be closed with 7-0 Prolene, nylon, or silk.

During wound closure, the crease height is repeatedly measured and compared with the contralateral side to verify symmetry; adjustment is always made toward the lower measurement of the two sides. It is not unusual to find that when one is finishing up on the second side, the crease height on the first side (which has been covered with ice or saline sponges) may measure half a millimeter lower. I do not use any buried crease-fixation suture, even in revisional cases.

Postoperative Care

Topical antibiotic-steroid ointment may be applied for 1 week. The eyelids are rested during the first 24 hours, with application of cold compresses. Sutures are usually removed 1 week after the procedure.

Problems and Complications

Problems associated with Asian eyelid crease procedures often involve asymmetry of the eyelid crease height, incomplete crease formation, or late obliteration of the crease. The reasons may include poor execution, poor knowledge, inadequate debulking of the soft tissues, marking the crease too high or low, or inadequate crease indentation. Factors that are somewhat beyond the practitioner's control include poor levator function that was not noted during clinical examination, a bleeding tendency, an allergy to medications, or infection.

Results

This 25-year-old Asian woman underwent primary Asian blepharoplasty. She is seen 2 months postoperatively.

This 35-year-old woman wanted a low-set parallel crease. She is seen 2 months postoperatively.

This 30-year-old woman had undergone a crease procedure elsewhere. Her preoperative findings included an excessively high crease, a prominent sulcus, and crease fold redundancy.

A beveled approach in a revisional upper blepharoplasty was done, with lysis of the adhesions through the orbicularis oculi and fibrous scar.

The postoperative view at 2 months (*right*) shows improvement in the sulcus and an overall lowering of the crease height. Skin shortage medially prevented a more ambitious correction; however, this can be remedied in the future when skin in this area develops more laxity.

Concluding Thoughts

Accurate definition of the crease height and shape determines the visible component of the procedure, as well as outcome and measurable success rate. A layered and selective debulking of the eyelid tissues makes the completion of these essential steps more reliable and efficient. Less hemorrhage and injury of tissues are encountered. It establishes the proper orientation and spatial geometry of the semirigid pretarsal skin and tarsus (or posterior lamella, vectored by the levator muscle) relative to the more passive preseptal and periorbital orbicularis (anterior lamella) when the eyelids are opened. Repositioning the preaponeurotic fat and resetting of the eyelid skin and forehead structures relative to the posterior lamella are critical steps in preventing complications. These measures allow the proper height and crease shape to be achieved as planned. It helps to soften the deepened sulcus appearance seen in revisional cases. Exact anastomosis of the levator aponeurosis to the lid crease incision along the superior tarsal border provides a higher probability for a successful outcome. Proper execution of these steps allows one to create a natural-looking eyelid crease without the use of permanent or buried static sutures.

The special niche of Asian eyelid crease procedures should progress from creating an eyelid crease that appears static (with the crease very apparent on downgaze) to a physiologically natural and dynamic crease (where it partially disappears on downgaze). I hope that surgeons who perform these procedures can appreciate these subtle goals to create a fluid crease for these special patients.

Clinical Caveats

Accurate definition of the crease height and shape determines the visible component of the procedure, as well as outcome and a measurable success rate.

A layered and selective debulking of the eyelid tissues makes the completion of these essential steps more efficient and reliable.

Repositioning the preaponeurotic fat and resetting of the eyelid skin and forehead structures relative to the posterior lamella are critical steps in preventing complications.

Exact anastomosis of the levator aponeurosis to lid crease incision along the superior tarsal border provides a higher probability for a successful outcome.

CHAPTER 30

Lower Eyelid Blepharoplasty

MARK A. CODNER, JUAN DIEGO MEJIA

Despite the frequency with which lower blepharoplasty is performed, the procedure remains a complex, challenging, and technically demanding one that should not be considered routine. Minimizing complications and maximizing postoperative results depend on careful preoperative planning and meticulous intraoperative technique. In addition to evaluating the eyelids, the surgeon must carefully assess the periorbital anatomy, including the midface, because midfacial aging can have a profound effect on the appearance of the lower lid. The lower lid and midface compose an aesthetic unit that is best treated together, and the standard lower lid approach provides an easy entry for midface rejuvenation. However, it is important to individualize the operative plan to address individual patient needs.

It is essential to identify risk factors and concomitant medical conditions that could contribute to postoperative complications. Excellent blepharoplasty results can be achieved through the combination of careful preoperative assessment and meticulous surgical technique using an anatomic approach to the aesthetic correction of aging changes of the eyelids and periorbital region. Traditional blepharoplasty techniques placed little emphasis on lower lid support or the correction of acquired anatomic changes of the surrounding periorbital region. Newer techniques emphasize lower lid support, such as routine canthopexy or canthoplasty, as well as transpalpebral elevation of the midface and fat preservation and repositioning. In our patients, routine canthal anchoring has been the key to achieving good, predictable results and avoiding complications.

Indications

Candidates for lower blepharoplasty are individuals with valid complaints in conjunction with physical findings that are amenable to surgical improvement. Typical complaints include a tired look, puffy lower eyelids, malar bags, wrinkled skin, an

accentuated lid-cheek junction, and a deep nasojugal groove. Patients must understand the importance of treating the lower lid–midface as an aesthetic unit. In most cases, treatment of one area without the other will produce unsatisfactory results.

Preoperative Assessment

Medical History and Evaluation

The first step in a thorough evaluation includes taking a history to identify specific conditions, including inflammatory eyelid disorders, Graves' disease, benign essential blepharospasm, and dry-eye syndrome. All of these increase the risk of complications after blepharoplasty and should be screened before surgery. These conditions are discussed in Chapter 28.

Medical Conditions That Might Increase the Risk of Complications

Blepharochalasis	Benign essential blepharospasm
Rosacea	Dry-eye syndrome
Pemphigus	Sarcoidosis
Graves' disease	Menopause

Physical Examination

To produce a result that will be aesthetically pleasing to the patient, the surgeon must take time to understand his or her complaints and concerns, and these should be confirmed by the physical examination. For example, patients complaining of lower eyelid bags may actually have midfacial aging or malar bags, which would not be improved with standard lower blepharoplasty techniques. Therefore the surgeon must be diligent in evaluating both the patient's complaints and the underlying anatomic findings to improve the aesthetic appearance of the periorbital region and provide the best possible outcome. The physical examination should proceed sequentially to ensure complete assessment of the periorbital anatomy. A Snellen eye chart is used to document preoperative visual acuity in all patients before blepharoplasty.

Eye Protection Mechanisms

Patients should be evaluated for the presence of Bell's phenomenon, since the combination of dry eyes with a poor Bell's phenomenon may lead to significant postoperative corneal dryness (*left*).

These patients should be further evaluated with Schirmer's test. The conjunctiva is anesthetized in the inferior lateral fornix with tetracaine eyedrops. Then the excess tear film is blotted with a cotton-tipped applicator, and a Schirmer's strip is placed in the lateral fornix while the patient maintains a forward gaze (*right*). Decreased tear production is present when less than 10 mm of the Schirmer's strip is wet after 5 minutes.

Eye Prominence

Prominent eye

Deep-set eye

The globe should be examined to evaluate its position relative to the bony orbit. Patients with prominent eyes have a negative vector, which is visible on the lateral view of the orbit when the anterior aspect of the globe is anterior to the underlying soft tissue of the infraorbital rim. Patients with deep-set eyes have a positive vector, where the globe is posterior to the infraorbital rim and overlying soft tissues.

A more detailed analysis can be performed with a Hertel exophthalmometer, which measures the position of the globe relative to the lateral orbital rim. Normal globe prominence is in the range of 16 to 18 mm; patients with enophthalmos have measurements less than 16 mm, and those with exophthalmos have measurements greater than 18 mm. Patients with deep-set eyes or prominent eyes are at increased risk for complications, and the degree of prominence influences the level at which the lateral canthus will be anchored during lateral canthoplasty.

In patients with a standard eye position (16 to 18 mm), the lateral canthal fixation should be in line with the inferior edge of the pupil to produce a normal eye fissure. Patients with prominent eyes (19 mm or more) exhibit a tendency for downward migration of the eyelid margin with lateral tightening, which will produce postoperative scleral show. Canthal anchoring in a standard position will “clothesline” the lid margin underneath the eye. In patients with mild prominence, supraplacement of the lateral canthal tendon is needed at the level of the midpupil. However, canthal anchoring in a higher position will impair upper lid closure. Therefore, with increasingly prominent eyes (as in patients with Graves’ disease), canthal anchoring should not surpass the midpupillary line; other techniques are needed, such as recession of the inferior retractors, insertion of primary spacers, or crisscross anchoring of the upper and lower lids. Patients with deep-set eyes (15 mm or less) need lower and deeper lateral canthal anchoring, because a standard canthal position can cause upward clotheslining of the lower lid, narrowing the eye fissure and reducing the size of the lateral scleral triangle.

Lower Lid Evaluation

The lower eyelid should be evaluated for lateral canthal descent, lower lid laxity, and the presence of scleral show, as well as excess skin and muscle, orbital fat, and malar bags. The presence of scleral show should be a red flag to the surgeon; this is often caused by a combination of a prominent eye, lower lid laxity, and poor infraorbital support. Adjunctive procedures should be considered, such as lateral canthal support, a possible midface lift, or orbital rim augmentation.

The eyelid should be evaluated for both shape and function. The lateral canthal position is normally 2 mm superior to the medial canthal position, and an imaginary line should be drawn from the medial to the lateral canthus indicating the canthal tilt.

A positive lateral canthal tilt is present when the lateral canthus is superior to the medial canthus; a negative lateral canthal tilt is present when the lateral canthus is inferior to the horizontal position of the medial canthus. A negative canthal tilt may indicate descent of the lateral canthus from disinsertion, laxity, or the presence of a prominent eye. These last patients are at increased risk for lid malposition and require lateral canthal support during blepharoplasty procedures.

The lid snapback test may indicate the presence of lower lid laxity; however, this is a fairly subjective test, and conclusions drawn from it may be inaccurate (*left*). More precise evaluation can be obtained by lid distraction. Anterior lid distraction should be less than 3 mm from the globe. Anything greater indicates lid laxity and postoperative risk for scleral show, ectropion, or corneal exposure. Appropriate lateral canthal anchoring can help reduce the risk in these cases (*right*).

Herniated Fat Pads

Usual areas of fat herniation and protuberance

Progressive weakening of the overlying septum as individuals age has been an accepted theory for the protrusion of the fat pads. Descent of the midface with aging also contributes to the unmasking of the lower eyelid bags as the interface between the lid and cheek becomes more apparent, leading to a “double-bubble” appearance. The lower lid has medial, central, and lateral fat prominences. The volume of these fat pads varies among patients. The surgeon should mark and document the most prominent fat pads preoperatively, because this can be difficult to do when the patient is on the operating table. The lateral fat pad is the most commonly overlooked pad in lower lid blepharoplasty, yet it generally contains the greatest volume and contributes most significantly to the lower lid bags. The options for managing the fat of the lower lid depend mostly on the amount of fat and on the characteristics of the lid-cheek junction. With this in mind, the fat pads can be preserved, removed, redistributed, or even augmented with autologous fat grafting.

Tear-Trough Deformity

The tear trough is a midfacial hollow that begins at the inner canthus and travels obliquely toward the lid-cheek junction. The orbitomalar ligament, along with the origin of the levator labii superioris and levator labii alaeque nasi muscles, contributes to its formation. Release of the orbitomalar ligament in the preperiosteal plane and fat transpositioning or grafting are effective for adding volume and improving this concavity.

Skin Pigmentation

Sometimes dark circles around the eyes are shadows produced by the convexity of the herniated fat, and these can be improved with blepharoplasty. However, many patients have pigmentation of the skin that will remain even after surgery, and it is important that the patient be told this. Use of hydroquinone may be effective to lighten dark circles caused by hyperpigmentation.

Midface

Aging changes in the midface are characterized by descent of the tissues, exposing the inferior orbital rim and allowing the postseptal fat to become more visible. Recognition of these changes is essential as the surgeon chooses the proper procedure. Transconjunctival fat removal alone without correction of vertical midface descent in these patients will lead to a skeletonized appearance of the lid-cheek junction. Patients with mild midface descent can benefit from extended blepharoplasty with release of the orbitomalar ligament with fat repositioning to produce a smoother lid-cheek junction. Those with more advanced aging changes and midface descent require a lower lid blepharoplasty combined with a midface lift.

Malar Eminence

Fat should be removed conservatively in patients with prominent cheekbones, because excessive resection will create a sunken lower lid appearance, accentuate the malar eminence, and disturb the balance of the lid-cheek junction. Patients with a lack of projection of the malar eminence are at greater risk for lower lid malposition after blepharoplasty. These patients can present with preexisting scleral show and prominent eyes. Canthal anchoring and lower lid release procedures are especially important in these cases to decrease the risk of complications.

Patient Education

All of the potential risks of surgery should be discussed with patients before blepharoplasty surgery. Common complications may include swelling, ecchymosis, chemosis, and lagophthalmos. Other possible complications include infection, hematoma, hypertrophic scarring, dry eye, epiphora, asymmetry, lid malposition, ectropion, entropion, and the rare risk of vision loss. Informed consent should include a detailed preoperative discussion of these risks with the patient.

Preoperative Planning

Classification of Periorbital Aging

A classification system of periorbital aging may aid in selecting the appropriate surgical procedure for correction. The classification is based on the anatomic findings associated with aging of the eyelids as well as midface descent, including the presence of tear-trough deformity, nasolabial folds, and bags under the lower lids. This classification system focuses on the relationship between the lower lid and the midface using an anatomic approach to develop a specific surgical plan.

Classification of Periorbital Aging

Type	Age-Related Changes	Appropriate Procedure
I	Excess fat, no skin excess	Transconjunctival blepharoplasty
II	Excess skin, muscle, and fat Changes above intraorbital rim Minimal lower lid laxity	Transcutaneous blepharoplasty Preperiosteal cheek lift Lateral canthopexy
III	Excess skin, muscle, and fat Descent of malar fat pad	Transcutaneous blepharoplasty Subperiosteal cheek lift
IV	Malar bags Significant lower lid laxity	Subperiosteal cheek lift Lateral canthoplasty

Type I patients demonstrate the earliest changes of periorbital aging, with findings confined to the lower eyelid. The presence of dermatochalasis includes acquired age-related excess folds of skin and muscle, along with apparent fat excess. However, the volume of orbital fat remains relatively unchanged from youth to middle age and is even resistant to volume loss in cachectic patients. In contrast, facial fat, including the malar fat pad and jowl, undergoes redistribution with age; that is, deflation and descent. The perception of increased orbital fat volume is often affected by the presence of edema. In type I patients, the focus is to improve the appearance of the eyelids by means of upper and lower blepharoplasty, including fat resection by a transconjunctival or transcutaneous approach and possible skin resection or resurfacing. Alternative procedures are also appropriate, including resetting or tightening the orbital septum and repositioning and retaining intraorbital fat.

Type II patients have a combination of lower lid aging and early evidence of midfacial descent. As the malar fat pad descends, the lid-cheek junction is more evident, with the inferior orbital rim becoming visible through attenuated soft tissue. Midfacial descent is often associated with loss of upper malar fullness, which contributes

significantly to the loss of lower lid support. These patients require augmentation of the infraorbital rim, either through arcus marginalis release and fat repositioning or elevation of the suborbicularis oculi fat (SOOF) to camouflage the infraorbital rim. Modified superficial midface-lift techniques with dissection in the supraperiosteal plane may be considered.

Type III patients display more advanced midfacial aging, with further descent of the lid-cheek junction and deepening of the nasolabial folds. Descent of the malar fat pad contributes to the formation of the nasolabial fold and requires elevation, either with a subperiosteal midface lift or combined face-lift procedures that elevate the malar fat pad.

Type IV patients have extensive midfacial aging changes, including malar bags, and often demonstrate lower lid malposition with lid laxity. Subperiosteal dissection is required, with release of the orbitomalar ligament, orbital retaining ligaments, and the subzygomatic space to elevate the midface, along with lateral canthal support to correct lower lid laxity.

Patient Preparation

Preoperatively the patient is instructed to stop taking all medications that increase the risk of bruising and swelling, including aspirin, ibuprofen, and vitamin E. Homeopathic herbs such as *Arnica montana* and bromelain may reduce postoperative edema and ecchymosis and have been used routinely for surgery patients for more than 15 years. Patients are instructed to carefully remove all makeup, particularly mascara residue, and to wash the face the morning of surgery. Lower blepharoplasty can be performed with a general anesthetic or with intravenous conscious sedation.

The patient should be placed in a reverse Trendelenburg position to decrease venous pressure. Surgical preparation includes application of a dilute povidone-iodine (Betadine) solution to the eyelids and face, taking care to avoid exposure of the conjunctiva; the eyes are irrigated with balanced saline solution before corneal protectors are placed.

Operative Technique

Anesthesia

Adequate intravenous or general anesthesia is obtained; preoperative antibiotic administration is recommended. Local anesthetic, consisting of lidocaine 1% with epinephrine 1:100,000, is injected with a 27-gauge needle into the lateral canthus, lower eyelid, and inferior orbital rim, avoiding the marginal arcades and the deep orbital structures to reduce the risk of eyelid or retrobulbar hematoma.

Markings

The lower lid incision is initially marked with a single point at the level of the lateral canthus. Markings should extend approximately 6 to 10 mm inferolaterally in a prominent crow's-feet skin line. Approximately 10 mm of skin should be preserved between the lateral extension of the upper and lower blepharoplasty incisions. Postoperative webbing or distortion can occur if these incisions are placed too close together. The remainder of the marking parallels the lid margin approximately 1 mm below the eyelashes.

Lower Lid Blepharoplasty

The lower lid skin is incised with a scalpel lateral to the canthus, exposing the underlying orbicularis oculi muscle, which is then divided with electrocautery into the submuscular space.

With the lower lid on stretch, scissors are used to dissect a subcutaneous tunnel over the pretarsal muscle just below the lashes, and with the same instrument the skin is incised, stopping 4 mm inferior to the punctum.

Through the lateral incision, the scissors are used once again to dissect a submuscular tunnel, and a second parallel incision is made through the orbicularis, preserving a 5 mm strip of pretarsal orbicularis muscle. Electromyographic analysis has revealed normal function to the pretarsal muscle strip with minimal risk of denervation. The skin-muscle flap is then dissected anterior to the septum with a Bovie cutting needle to the level of the infraorbital rim. Dissection continues past the infraorbital rim just superficial to the periosteum, releasing the orbitomalar ligament to improve the appearance of the lid-cheek junction.

Submuscular dissection continues over the septum down to the orbital rim. The orbitomalar ligament is divided along the entire infraorbital rim. A tear-trough deformity requires release of the medial origins of the orbicularis oculi, levator labii superioris, and levator alaeque nasi muscles from the inferior orbital rim. Once the orbitomalar ligament is released, the SOOF becomes visible, and dissection superficial to the periosteum is continued approximately 10 mm below the orbital rim, preserving the zygomaticofacial and zygomaticotemporal nerves. Release of the orbitomalar ligament allows elevation of the SOOF with the skin-muscle flap. Elevation of the SOOF with orbicularis muscle redraping camouflages the inferior orbital rim, giving the lid-cheek junction a smoother appearance.

Fat can be removed conservatively with the Bovie from all three lower lid compartments, and the orbital septum is resected along with excess fat (*left*). Removal of the septum may reduce the risk of subsequent septal scar formation. If fat resection is planned, the arcuate expansion of Lockwood's ligament between the central and lateral fat pad should be preserved for additional support to prevent further herniation of periorbital fat. When fat transposition is the objective, Lockwood's ligament should be divided to allow adequate release and redraping of the fat pads.

Care should be taken to avoid injury to the inferior oblique muscle between the nasal and central fat pads. The inferior oblique muscle is reportedly the most common extraocular muscle injured during blepharoplasty, usually from indiscriminate cauterization. The lateral fat pocket should be reevaluated after lateral canthopexy, because lateral tension will cause additional herniation.

Alternative procedures might also be considered: arcus marginalis release, septal reset, or septal tightening. Septal reset, as described by Hamra, involves suturing the septum orbitale over the inferior orbital rim to produce a youthful convex contour to the lower eyelid–cheek complex. Septal tightening, described by de la Plaza and Mendelson, encompasses suture tightening of the septum after partial resection or septal plication without resection. These procedures are designed to improve the pseudoherniation of the orbital fat through the septum. As in an upper blepharoplasty, the lower lid should be irrigated with normal saline solution after resection of the orbital fat pads.

Lateral Canthal Support

The degree of lower lid laxity should be evaluated intraoperatively by placing anterior traction on the lower eyelid away from the globe and measuring the amount of lid distraction with calipers. Lid distraction of 1 to 2 mm indicates minimal lid laxity; 3 to 6 mm indicates moderate laxity; more than 6 mm indicates significant lid laxity.

Routine lateral canthal anchoring is performed as part of all of our lower blepharoplasties. A lateral canthopexy is indicated in patients with minimal or moderate lid laxity. When lid distraction is more than 6 mm from the globe or when persistent intraoperative lid laxity is seen after a routine canthopexy, horizontal shortening of the lid is performed with a lateral canthotomy and canthoplasty. Regardless of the type of anchoring used (canthopexy or canthoplasty), the internal vector of fixation is essential. The canthus should be anchored inside the orbital rim to enable the lid to conform to the globe.

The vertical position at which the lateral canthal fixation suture will be placed depends on the degree of eye prominence, the amount of lower lid laxity, and the preoperative shape of the lower eyelid. The preoperative shape of the lower eyelid must be carefully maintained, avoiding overcorrection or alteration of the preoperative canthal position. In patients who have normal eye prominence, the position of the lateral canthal suture is most commonly at the inferior edge of the pupil.

However, patients with prominent eyes require supraplacement of the canthal support suture at the level of the midpupillary line, with overcorrection and minimal tightening to avoid downward clotheslining of the lower lid below the inferior limbus, which can cause scleral show. The release of the inferior retinaculum and lower lid retractors facilitates the supraplacement of the canthus. The downward force of the prominent globe on the lower lid will cause descent of the lid margin after lateral canthal anchoring; however, this force does not exist in patients who have deep-set eyes. Patients with deep-set eyes require more inferior and posterior placement of the canthal suture to avoid upward clotheslining, with care to avoid overcorrection.

The objective of lateral canthopexy is to suture the tarsal plate and lateral retinaculum to the periosteum of the lateral orbital rim, thereby tightening the lower lid tarsoligamentous sling. Through the blepharoplasty incision, a horizontal mattress suture of 4-0 Mersilene is used to incorporate the tarsal plate and lateral retinaculum. To prevent dehiscence of the Mersilene through the tarsus, an interlocking 6-0 Vicryl suture is placed around the 4-0 Mersilene. The Mersilene suture is then placed inside the lateral orbital rim periosteum from deep to superficial, which allows the lateral canthus and lower lid to be tightened posteriorly and superiorly to maintain the position of the lower lid margin against the globe.

A single tie is placed on the lateral canthal suture to set the correct tension as the lower lid assumes its desired position. Before completing the knot, lower lid laxity is once again evaluated with a pair of fine pickups. At this point, the lower lid should have a normal distraction of 1 to 2 mm, and it should allow some upper and lower displacement without restriction. If this is the case, the canthopexy knot is completed. When the lid is too tight and does not permit displacement above the lower limbus with the pickups, the knot should be loosened.

Patients who have significant lid laxity with lid distraction greater than 6 mm, or those with persistent intraoperative lid laxity after canthopexy, require lateral canthotomy and canthoplasty. Lateral canthoplasty is performed after canthotomy of the inferior limb of the lateral canthal tendon, followed by cantholysis, which allows mobilization of the lower lid. Before the lid is transposed over the lateral orbital rim, 2 to 3 mm of full-thickness horizontal lid shortening is performed to correct significant lid laxity. A 4-0 Mersilene suture is used for lateral canthoplasty and is placed

through the edge of the tarsal plate from inferior to superior, ensuring vertical alignment while controlling lash rotation. The mattress suture is then placed along the posterior aspect of the lateral orbital rim periosteum at the appropriate level according to eye prominence and is tied in a surgeon's knot. The desired amount of tension created by the lateral canthoplasty should allow 1 to 2 mm of lid distraction away from the globe, and the lid should be easily mobilized over the cornea. Over-tightening of the lateral canthoplasty should be avoided to minimize lid malposition. The lateral commissure is then reconstructed with a 6-0 plain catgut suture placed in the gray line to prevent postoperative lateral canthal webbing. To re-create a normal-appearing lateral commissure, the suture is placed in the posterior aspect of the upper lid gray line and the anterior aspect of the lower lid gray line to allow the upper lid to slightly overlap the lower lid in a normal anatomic relationship.

After lateral canthal support is achieved, the skin-muscle flap is redraped in a superior lateral vector. A triangle of excess skin and muscle is resected according to the amount that overlaps the lateral extent of the lower blepharoplasty incision.

The orbicularis muscle flap is then resuspended to the lateral orbital rim at the level of the lateral canthus using a 4-0 Vicryl suture, which is placed as a three-point quilting suture from the incised edges of skin and muscle to the periosteum along the inner aspect of the lateral orbital rim to recreate the normal concavity associated with the lateral orbital raphe. Similarly, interrupted absorbable sutures are placed in the lateral cut edge of the orbicularis flap to the lateral orbital rim periosteum and temporalis fascia to resuspend the orbicularis under appropriate tension. Resuspension of the orbicularis provides additional lower lid support as well as elevation of the SOOF over the inferior orbital rim, anatomically blending the lid-cheek junction and giving it a smoother look.

Minimal skin and muscle are resected parallel to the lower lid margin to minimize the risk of lid malposition. A small strip of orbicularis is removed from the skin muscle flap to avoid a redundant layer overlying the preserved pretarsal orbicularis. Tension-free closure is then performed in the skin muscle edges with a 6-0 fast-absorbing catgut suture.

Adjunctive Techniques

Treatment of the Tear Trough Deformity

The tear trough hollow can be corrected during a standard lower blepharoplasty. When releasing the orbitomalar ligament along the infraorbital rim, the surgeon performs additional preperiosteal dissection and release of the tear trough. This dissection is performed with low-power electrocautery and should be limited to prevent injury to the buccal branch of the facial nerve, which is located medial to the tear trough at the level of the angular artery. If the levator labii superioris alaeque

nasi muscle twitches with the electrocautery, this may be a sign of overdissection near the buccal branch. After release of the tear trough, the nasal fat pad is transposed and secured with a 6-0 Vicryl suture into the periosteum. It is important to remember that aggressive transposition of the nasal and central pads can impair inferior oblique function and result in diplopia. Fat grafting from excised orbital fat can also be used to fill this space.

Postoperative Care

At the end of the procedure, a 6-0 nylon suture can be placed as a temporary tarsorrhaphy along the gray line lateral to the limbus. Another option is to place a temporary Frost suture in the lower lid margin lateral to the lateral limbus and either suturing to the eyebrow or suspending to a Steri-Strip above the eyebrow. These techniques will reduce corneal exposure in the immediate postoperative period and minimize chemosis. These sutures are removed at the first postoperative visit 5 to 7 days after surgery.

Postoperatively the patient's head should remain elevated to reduce edema and ophthalmic pressure. An ice pack or cold compresses should be applied to the eyelids for 48 hours. The eyes should remain lubricated at all times with saline drops during the day and lubricating ointment at night. Lagophthalmos can be caused by periorbital edema; if this occurs, it resolves spontaneously in 1 to 2 weeks. In these cases eye drops and ointment are essential to prevent corneal abrasions and exposure problems. Before discharge the patient's vision should be evaluated and documented. Any signs of corneal irritation or decreased visual acuity require careful ophthalmologic evaluation, including slit-lamp examination with the use of fluorescein eyedrops to evaluate the cornea. Patients are asked to avoid the use of contact lenses and any eyelid makeup on the suture lines for 2 weeks after blepharoplasty.

Persistent postoperative chemosis can be treated with liberal application of ophthalmic ointments and steroid eyedrops. Use of these eyedrops should be limited to 2 weeks to avoid the risks associated with prolonged treatment. Severe chemosis that herniates through the palpebral fissure requires more aggressive management with liberal use of ophthalmic ointment, topical steroids, patching the eye closed for 24 to 48 hours, conjunctivotomy, or tarsorrhaphy.

Mild lid malposition may contribute to lagophthalmos and corneal exposure, which may require bandage contact lenses to protect the cornea and conservative massage of the lower lid margin until the patient has passed the critical 6-week postoperative period, which corresponds with the peak inflammatory phase of healing. Lower lid ectropion or persistent lid malposition after a 6 week period of conservative management may require surgical intervention including placement of a posterior lamella spacer graft and lateral canthoplasty.

Outcomes

Lower blepharoplasty can no longer be considered a routine operation. Surgical techniques have evolved and are today significantly more sophisticated than in previous decades. Careful preoperative evaluation is the initial step toward creating a specific and comprehensive treatment plan for each patient based on individual findings and desired outcome. Patients who have medical or anatomic characteristics known to be factors predictive of poor outcome should be considered high-risk patients who require alternative procedures to minimize complications. Once assessment and planning are complete, blepharoplasty procedures should be performed with precision. Emphasis is placed on maintaining the preoperative shape of the palpebral fissure with particular attention to maintaining lower eyelid position. Lateral canthal support, most commonly with lateral canthopexy, represents a very important step in the technique to maintain lid shape and reduce the risk of lower lid malposition or postoperative round-eye syndrome. The tradeoff, which should be discussed with the patient before surgery, is that the lower lid may appear tight, and this could last 2 to 3 weeks after surgery. The natural S-shaped curve of the lower lid and the palpebral aperture are preserved after healing is complete.

Complications associated with lateral canthoplasty have been minor and primarily include canthal angle webbing or asymmetry that requires surgical revision. The risk of frank ectropion is significantly minimized with the use of lateral canthal support. In addition to minimizing the risk of complications, maximizing the aesthetic result is directly related to management of both periorbital fat compartments, the orbicularis muscle, and SOOF. Elevation of the skin muscle flap and release of the orbito-

malar ligament mobilize the SOOF, which is elevated with the orbicularis muscle. Using the orbicularis muscle as a sling with secure lateral orbital fixation is the key to maximizing the aesthetic appearance of the infraorbital region. This can be performed safely based on the anatomy of the lower eyelid. The posterior lamella (tarsoligamentous sling) has a separate point of periosteal fixation from the anterior lamella (skin-muscle flap). These basic principles, founded on anatomy, are the two key points in maximizing surgical outcome after lower blepharoplasty. Adherence to these basic principles significantly contributes to achieving the overall goal.

Complications

Lower Lid Malposition

Lower lid malposition is the most common surgical complication after transcutaneous lower lid blepharoplasty and includes lid retraction, scleral show, and ectropion. The incidence of this complication varies from 5% to 30% in the literature. Lower lid malposition not only detracts from the aesthetic results but can also lead to functional problems such as exposure keratopathy. The most common etiologic factor is vertical deficiency of the anterior or posterior lamella in patients with pre-existing tarsoligamentous laxity. Care should be taken to avoid excessive skin and muscle resection. Patients associated with increased risk include those with lower lid laxity, prominent eyes, negative vector, negative canthal tilt, and preoperative scleral show. To avoid this complication, some have suggested less-invasive approaches to the lower lid, such as the transconjunctival lower blepharoplasty. Although more conservative, this technique does not eliminate the risk of lower lid malposition. In addition, most patients who consult for lower lid rejuvenation need removal of excess skin and muscle, which is a limitation of the transconjunctival approach. The treatment of postoperative mild lower lid malposition is conservative, with postoperative massage, the use of tape to hold the lower lid in position, and eye lubrica-

tion. If conservative treatment fails to improve the position of the lower lid after 6 weeks, surgical revision with canthopexy or canthoplasty with or without the use of spacers is recommended. Drill hole canthal anchoring is often needed, because there might be a lack of adequate periosteum for suture fixation. Severe postoperative lower lid malposition causing functional problems or corneal exposure requires immediate correction to avoid exposure keratopathy.

The addition of routine lateral canthal anchoring provides an anatomic solution for decreasing the risk of lower lid malposition after transcutaneous blepharoplasty. In a review of our 10-year experience with routine lateral canthal support in 264 primary cosmetic transcutaneous lower lid blepharoplasties, we reported ectropion in 0.8%, lower lid retraction requiring revision in 2.7%, and mild lower lid retraction (1 mm or less) that resolved with massage in 6.1%. Patients who needed revision were treated with secondary canthoplasty; three patients required posterior lamella spacer grafts.

Causes of Postblepharoplasty Lower Lid Malposition

Lower lid laxity	Middle lamellar scarring
High risk patients	Posterior lamellar scarring
Excessive skin removal	Damage to pretarsal orbicularis muscle
Excessive muscle removal	Untreated hematoma

Chemosis

Chemosis is the most common nonsurgical complication after lower blepharoplasty, occurring in up to 12% of patients undergoing the procedure. It is a transudative edema of the bulbar or fornical conjunctiva and is characterized by visible swelling of the conjunctiva.

Patients may experience epiphora, irritation, foreign body sensation, and mild visual alteration. In a lower blepharoplasty, the causes include conjunctival desiccation from exposure, regional edema, and lymphatic stasis resulting from local trauma. Chemosis usually presents in the first postoperative week. The median duration is approximately 4 weeks and can range from 1 week to 3 months.

Prevention is the most important treatment in chemosis management, and it starts in the operating room. The use of lubricated corneal protectors, preventing prolonged eye exposure and dryness with frequent moisturizing of the eyes, and minimizing trauma can all help reduce its incidence. If significant chemosis is seen intraoperatively, it can be treated with an immediate conjunctivotomy with a pair of small scissors. A temporary tarsorrhaphy suture can be placed lateral to the lateral limbus to reduce postoperative chemosis.

Postoperative treatment of chemosis starts by keeping the eyes lubricated with wetting drops and ophthalmic lubricants. Ophthalmic steroid drops (tobramycin/dexamethasone [Tobradex; Alcon]) are also helpful. If the irritation does not resolve, an eye patch to the affected eye with the use of an ACE bandage at night can be used. In more severe cases (lasting more than 2 weeks), especially if lagophthalmos is present, a conjunctivotomy or tarsorrhaphy should be considered.

This patient presented with postoperative chemosis that prolapsed through the eyelids during closure, causing lagophthalmos. A conjunctivotomy of the prolapsed conjunctiva with the patient under local anesthesia was performed in an office setting.

This patient, seen before and immediately after a conjunctivotomy with the use of a local anesthetic in the office, shows an almost complete resolution of her chemosis.

Visual Changes

Visual changes such as diplopia are generally temporary and can be attributed to edema. The most common extraocular muscle damaged in lower blepharoplasty is the inferior oblique muscle, which is located between the nasal and central fat pads and can be inadvertently injured during fat manipulation. Conservative treatment is recommended; normal vision is usually regained when the muscle edema subsides. Vision loss can also occur; it is discussed in Chapter 28.

Other Complications

Epiphora is usually a transient problem that can resolve spontaneously in days; it is most commonly caused by edema distorting the lacrimal canaliculi. If persistent, punctal eversion can be corrected by excising and closing an ellipse of conjunctiva below the canaliculus, producing inversion. The same effect can be obtained by applying cautery below the lacrimal canaliculus on the conjunctival side to produce contraction and inversion of the punctum.

Corneal abrasions can be prevented by constant corneal lubrication, the use of ocular protectors, and avoiding prolonged exposure of the cornea. Dry-eye syndrome, infection, and hematoma may occur; these are discussed in Chapter 28.

Results

The following cases represent a variety and continuum of patients who demonstrate age-related changes of the eyelids and periorbital region.

This patient, with early signs of aging confined to the upper and lower eyelid with excess skin, muscle, and fat, is shown before and after upper and lower blepharoplasty.

This woman, with a tear-trough deformity of the lower eyelid, shows improvement after release of the orbitomalar ligament, orbicularis, and levator labii superioris, along with fat transposition into the tear trough.

This patient had prominent eyes, with a Hertel measurement greater than 18 mm; she is shown after a blepharoplasty with canthopexy to support the lower eyelid, thus minimizing the risk of lower lid malposition.

This woman underwent lateral canthopexy and lateral canthoplasty; her lower lid shape and lateral canthal position were maintained.

This closeup view of the lateral canthus after lateral canthopexy and lateral canthoplasty demonstrates the natural appearance of the lateral palpebral aperture and commissure.

This woman, with significant signs of midfacial aging, is shown after upper and lower blepharoplasty combined with subperiosteal midface elevation.

This patient underwent bilateral lower blepharoplasty. Her tear trough deformity was corrected by orbitomalar ligament release and repositioning of the nasal and central fat pads.

Concluding Thoughts

As concepts of aging evolve and new techniques are developed, operative approaches to blepharoplasty continue to be refined, thereby producing a more natural, youthful eyelid appearance. The stigmata of surgery can be minimized, along with the risk of complications, by proper preoperative assessment and meticulous surgical technique. Appreciation of the underlying anatomy, along with the indications and limitations of techniques used to correct the anatomic changes that occur with aging, form the basis of a sound surgical approach that ensures favorable results.

Clinical Caveats

Preoperative evaluation should include the lower lids and midface.

This technique for lower blepharoplasty is an anatomically based procedure that requires familiarity with periorbital anatomy.

Preoperative recognition of high-risk patients is essential; this can be achieved with systematic clinical evaluation.

Patients at high risk for lower lid malposition include those with prominent and deep-set eyes, lower lid laxity, a negative canthal tilt, and a negative vector.

Modifications of the surgical technique are performed based on the extent of the age-related changes present in the eyelids and periorbital region.

Lower blepharoplasty using a skin-muscle flap can be safely performed with minimal risk of denervation of the pretarsal orbicularis muscle.

Release of the orbitomalar ligament is an important part of lower lid blepharoplasty to resuspend the orbicularis and elevate the SOOF to achieve a smoother transition of the lid-cheek junction.

Routine lateral canthal anchoring is required to minimize the risk of postblepharoplasty lid malposition.

Modest lower lid laxity with less than 6 mm of lid distraction is managed with lateral canthopexy.

Significant lower lid laxity of 6 mm or more of lid distraction is managed with lateral canthoplasty.

Lower lid malposition is the most common surgical complication after lower lid blepharoplasty. Chemosis is the most common nonsurgical complication after lower lid blepharoplasty.

Annotated Bibliography

Carraway JH, Mellow CG. The prevention and treatment of lower lid ectropion following blepharoplasty. *Plast Reconstr Surg* 85:971-981, 1990.

Ectropion and scleral show are the most common complications after lower lid blepharoplasty. The authors discuss preoperative evaluation, operative techniques, and postoperative measures to prevent postblepharoplasty ectropion. Postoperative treatment is also addressed.

Hamra ST. Arcus marginalis release and orbital fat preservation in midface rejuvenation. *Plast Reconstr Surg* 96:354-362, 1995.

With aging, the periorbital area reveals progressive exposure of the underlying skeletal anatomy as compared with the lower areas of the face, where thicker soft tissues continue to cover underlying bony landmarks. The author describes a technique to preserve lower eyelid fat and to advance it beyond the infraorbital rim. This procedure is especially indicated in secondary procedures correcting overresection of orbital fat or deformities resulting from malar augmentation.

Jelks GW, Jelks EB. The influence of orbital and eyelid anatomy on the palpebral aperture. *Clin Plast Surg* 18:183-195, 1991.

The authors discuss the multitude of factors influencing the palpebral aperture. Unique individual combinations of the orbital anatomic influences cause the variations in the palpebral apertures.

The superficial lateral canthal tendon: anatomic study and clinical application to lateral canthopexy. *Plast Reconstr Surg* 109:1149-1157; discussion 1158-1163, 2002. *Most patients who undergo facial cosmetic surgery procedures that could cause lower eyelid retraction or ectropion should have an additional surgical procedure to support the lower eyelid and lateral canthus. Suspending the lateral canthus by surgically altering the lateral canthal tendon is a proven technique that can provide support for the lower eyelid, but a technique of this complexity may be unnecessary for most patients. The authors investigated the attachments of the lateral canthus to the lateral orbital rim and found that the most commonly appreciated attachment between the eyelids and the lateral orbital rim is the lateral canthal tendon (the lateral canthal raphe). However, the lateral canthus also is attached to the orbital rim at a more superficial level through the septum orbitale. This superficial fascial plane may be modified and used as a structure to stabilize or suspend the lateral canthus. This structure is defined in this article as the "superficial lateral canthal tendon."*

CHAPTER 31

Transconjunctival Blepharoplasty

FOAD NAHAI

Evolution of Technique

In an effort to minimize the risks associated with the open or transcutaneous skin-muscle approach to blepharoplasty, there has been renewed interest in the transconjunctival approach. Originally described by Bourguet in 1928, the transconjunctival approach was reintroduced in 1973 by Tessier for removal of fat from the lower eyelid and treatment of congenital deformities and trauma. This approach was later popularized for the removal of lower lid fat by Baylis et al, by McCord and Moses in the oculoplastic literature in the 1980s, and by Zarem and Resnick in the plastic surgery literature in the early 1990s. These surgeons emphasized the safety of this technique and the significant reduction in complications it offered, with almost complete elimination of lid retraction and its consequences. My personal experience, reported in 1995 and again in 2010, confirmed the safety and efficacy of this approach for removal of fat from the lower eyelid. Over time, interest in transconjunctival blepharoplasty waned as the focus shifted to amelioration of aging of the lid-cheek junction with an emphasis on fat redraping and the transpalpebral approach to mid-face elevation. Today, however, the transconjunctival approach is again attracting attention and gaining in popularity, not only for fat removal from the lower eyelid but also for fat redraping, fat redistribution, and a transconjunctival gateway to the mid-face. In 1999 we described the transconjunctival approach to the medial or nasal fat pocket of the upper eyelid.

Advantages

In addition to the obvious benefit of significantly decreasing complications, the other advantage to this technique is that there is no visible scar. Lid retraction and its consequences—exposure, round eye, scleral show, and ectropion—have all but been eliminated with this approach. Baylis et al reported no lid retraction, as did Zarem and Resnick. A personal review of 300 consecutive blepharoplasties between March 1992 and March 1996 (portions of which were published in 1995) included 120 transconjunctival blepharoplasties and 180 transcutaneous blepharoplasties. The overall complication rate for the transconjunctival group was 5% and for the transcutaneous group 13%. In the transconjunctival group there was no lid retraction, and in the transcutaneous group 3.3% had lid retraction. The revision rate for the transcutaneous group was 2.2%, and for the transconjunctival group it was 1.6%. The complication rates were similar in primary and secondary blepharoplasties.

Transconjunctival and Transcutaneous Blepharoplasties: A Personal Series of 300 Patients (March 1992–March 1996)

	Transconjunctival	Transcutaneous
Primary blepharoplasty	101 (84%)	145 (80%)
Secondary blepharoplasty	19 (16%)	35 (20%)
Mean follow-up	3 yr	3 yr
Range	2-4 yr	2-4 yr

Transconjunctival and Transcutaneous Blepharoplasties: Complications (March 1992–March 1996)

Complication	Transconjunctival (N = 120)	Transcutaneous (N = 180)
Surgical revision	2 (1.6%)	4 (2.2%)
Exposure	0	8 (4.4%)
Subconjunctival hematoma	2 (1.6%)	4 (2.2%)
Infection	0	2 (1.1%)
Granuloma	2 (1.6%)	0
Scleral show/ectropion	0	6 (3.3%)
Overall	6 (5%)	24 (13%)

Disadvantages

Resection of excess skin and muscle is not possible through this approach, although the addition of a pinch excision adds a viable option for dealing with the excess skin. Access for redraping and redistribution of periorbital fat and access to the midface are possible through this approach, but it is not as straightforward as the open approach. In the upper eyelid, only the nasal fat pocket can be approached through the conjunctiva, which limits its role to removal of fat from that pocket only.

Management of Fat in the Eyelids

Over the years there has been considerable change in our management of periorbital fat. Gone are the days of the skin-muscle-fat excision blepharoplasty. It was through this evolution of fat management around the eye in the late 1990s that transconjunctival fat removal became less popular in general, and I chose it with significantly less frequency in my practice. My current management of lower lid fat is presented in the graphs and includes the following:

- Redraping
- Preservation
- Excision
- Augmentation

Even in the upper eyelid, I am preserving fat rather than resecting, especially in the lateral pocket.

Indications

Fat management, especially in the lower eyelid, is now customized to each individual. I base my options for fat management on the amount of fat present and an evaluation of the lid-cheek junction. If the patient has little if any aging of the lid-cheek junction with true excess fat, I prefer resection of fat. If the patient has no excess fat, the fat pocket is not opened. If the patient has aging of the lid-cheek junction and sufficient fat for redraping, redraping or redistribution of that fat is the procedure of choice. In patients who require improvement of the lid-cheek junction and do not have an adequate volume of lower lid fat, augmentation with autologous fat or a dermis graft is necessary.

For individuals with excess lower lid fat and little or no lid-cheek junction change, the postseptal transconjunctival approach is an ideal operation with safe, easy fat removal from all compartments. It is also a good operation for patients with excess fat and fine skin wrinkling and in those with apparent excess skin in whom fat removal will result in redraping of the excess skin into an acceptable contour with elimination of the skin laxity. Laser resurfacing and peels have been advocated for skin tightening after transconjunctival fat removal to deal with the excess skin; however, I have found that skin excision is best for handling the excess skin. The combination of transconjunctival fat removal and skin excision through *skin-pinch blepharoplasty* is a suitable alternative to the transcutaneous skin-muscle flap blepharoplasty in selected patients. For candidates for redraping or redistribution or augmentation of the periorbital fat, the preseptal transconjunctival approach allows access to the periorbital fat, retroorbicularis oculi fat, and midface. This approach does not afford the same easy access and visualization of the transcutaneous approach.

Preoperative Assessment

A complete medical history is taken. We ask about hypertension and medications that affect bleeding. A careful ophthalmologic history is then obtained. The patient is asked about any history of eye problems or operations, specifically inquiring about glaucoma and Lasik procedures, symptoms of dry-eye syndrome or irritation, whether he or she wears glasses or contact lenses, and any family history of eye problems, especially glaucoma.

The examination includes an evaluation of the lower lid skin, muscle, fat, and lid-cheek junction. Lid tone should be assessed with the pinch and traction tests. Schirmer's test is done on a selective basis, as indicated. Although I routinely measure every patient's eyes with the Hertel ophthalmometer, it may not be as vital to do so for patients undergoing transconjunctival procedures.

Upper Eyelid

Pertinent Anatomy

The only fat compartment to herniate in the upper eyelid is the medial compartment. The other compartment is retained anatomically, does not herniate, and cannot be exposed through the conjunctiva.

We consider the upper eyelid to be divided into tarsal and orbital portions at the level of the supratarsal fold, which is located 3 to 5 mm above the upper border of the tarsal plate in whites and much lower in Asians. It is formed by the fusion of the levator aponeurosis, orbital septum, and fascia on the deep surface of the orbicularis oculi muscle. This fused layer acts as a sling and holds up the periorbital fat so that the excess fat drapes over the fold rather than herniating below it.

This sling is lower laterally and much higher nasally, thus allowing herniation of the nasal fat pocket below it. The other structure of importance here is the levator aponeurosis. The lateral horn of the levator is much lower than its medial horn. These two factors combined allow transconjunctival access to the nasal or medial fat pocket without risk of injuring or involving the levator aponeurosis.

The medial or nasal fat lies medial to the levator aponeurosis and below its medial horn. The lateral temporal or central upper eyelid fat pocket lies anterior to the levator aponeurosis and is inaccessible through the transconjunctival approach. The medial or nasal fat is usually pale yellow or white. It contains more sensory filaments, branches of the supratrochlear nerve, and more blood vessels, branches of the superior ophthalmic artery. The fat of the lateral central or temple compartment is much more yellow in color and has sensory fibers and vascular branches of the supraorbital nerve and artery.

Transconjunctival Approaches

Only the nasal fat pocket can be approached through the medial conjunctiva below the medial horn of the levator aponeurosis through the so-called bare area described by Guerra et al.

Preoperative Planning

The transconjunctival approach is suitable for a primary and secondary procedure for removal of excess medial upper eyelid fat. The best candidates for this procedure have excess fat limited to the nasal pocket with little or no true skin excess. In my experience, most of these patients have undergone previous blepharoplasties, with remaining excess fat in the medial or nasal pocket.

Markings

With gentle pressure on the globe, I look for the maximum bulging of the medial fat pocket and place a small mark on the skin.

Operative Technique

Anesthesia

Local anesthesia is my choice if fat removal is the only procedure to be performed. If it is combined with other facial rejuvenation procedures, I prefer general anesthesia. Before injection of the local anesthetic, 1 to 2 drops of topical tetracaine anesthetic are placed on the eye. The local anesthetic, 0.5% lidocaine with epinephrine, 1:200,000, is infiltrated transcutaneously and through the conjunctiva. If the patient is under general anesthesia, the lidocaine-epinephrine mixture is injected for its vasoconstrictor effect, but the tetracaine is not necessary.

Incision

A corneal protector is placed over the eye. The medialmost part of the upper eyelid is retracted; I prefer to use a Blair retractor. The “bare area” is immediately exposed and an incision made in the conjunctiva with Colorado tip needle electrocautery. This incision is kept in the medialmost part of the upper eyelid and should not extend laterally beyond the bare area, where it may injure the levator aponeurosis and risk postoperative ptosis. Once the incision is made, I take a pair of fine blunt-tipped scissors and spread the blades. The nasal fat pocket immediately comes into view.

Fat Excision

The medial fat pocket is then easily teased and delivered through the incision, where it is trimmed with the electrocautery. The endpoint is reached when there is no bulging medially in the upper eyelid with gentle pressure on the globe.

Closure

The conjunctival incision is always left open.

Postoperative Care

The patient's head is elevated, and ice packs are placed on the eyelids.

Results

The transconjunctival approach for removal of fat in the upper eyelid has been free of complications in our hands, specifically no eyelid ptosis. There have been no revisions, and patients have been consistently pleased.

This middle-aged woman underwent an endoscopic brow lift, transconjunctival removal of fat from the upper eyelids, a lower lid blepharoplasty with transpalpebral midface lift and neck lift, and laser resurfacing of the forehead. She is seen 12 months postoperatively. No skin was removed from the upper eyelids; the improvement seen in the upper lids resulted from the endoscopic brow lift and excision of fat from the medial fat pocket.

This 50-year-old woman underwent an endoscopic brow lift, transconjunctival removal of fat from the upper eyelids, lower lid blepharoplasty, and a face and neck lift. She is shown 3 years after surgery. No skin was removed from the upper eyelids. The medial upper lid improvement that resulted from transconjunctival fat removal is most evident in the split-face view.

This woman in her early fifties had had a previous coronal brow lift. She underwent an endoscopic brow lift with transconjunctival removal of fat from the nasal pocket of the upper eyelids. The upper eyelids are improved as a result of the transconjunctival removal of fat from the nasal pocket and the endoscopic brow lift. There was no skin excision from the upper eyelids.

Lower Eyelids

Pertinent Anatomy

An understanding of the anatomic relationships between the fat pockets and other lid structures is the key to this approach. It should be remembered that the outer lamella of the lower eyelid is composed of the skin and orbicularis muscle. The middle lamella is the orbital septum, and deep to it is the periorbital fat; the posterior lamella behind the orbital fat is made up of the lower lid retractors (capsulopalpebral fascia) and conjunctiva.

Orbital Fat Pads

The orbital fat pads are bounded anteriorly by the orbital septum. The septum is attached inferiorly to the arcus marginalis and fuses superiorly with the lower lid retractors. The orbicularis muscle and skin are anterior to the septum. The orbital fat pads are bounded superiorly and posteriorly by the lower lid retractors. The lower lid retractors arise from the terminal muscle fibers and tendons of the inferior rectus muscle. They fuse with the orbital septum 5 mm below the inferior tarsus and insert on the tarsal plate. The posterior lower lid retractors are applied very close, in fact quite adherently, to the lower lid conjunctiva.

The inferior oblique muscle lies within the orbital fat and is the only eye muscle at risk during blepharoplasty. The muscle originates along the anterior medial orbital floor, passing posteriorly and laterally beneath the globe separating the medial and central fat pockets.

The Compartments

The central compartment is separated from the lateral compartment by the arcuate expansion of the inferior oblique muscle, which inserts into the orbital rim anterolaterally. The inferior oblique muscle separates the central and medial fat compartments.

Transconjunctival Approaches

Transconjunctival approaches to the lower eyelid are either preseptal or postseptal. Each approach has its own advantages and limitations. The postseptal approach only allows fat removal. The preseptal approach allows access for fat removal and redistribution, along with access to the midface and orbital rim.

Transconjunctival Approaches

The preseptal approach allows:

- Fat removal
- Fat redistribution
- Access to midface

The preseptal incision is placed:

- Below the tarsal border
- At the level of the upper arcade

The postseptal approach allows:

- Fat removal only

The postseptal incision is placed:

- In the fornix 4 to 5 mm below the tarsal border
- At the level of the lower arcade

Postseptal Approach

Transconjunctival blepharoplasty by the postseptal approach permits access to the orbital fat through an incision in the conjunctiva and lid retractors/capsulopalpebral fascia without any disruption or involvement of the skin, muscle, or orbital septum. The incision is usually made in the conjunctiva of the inferior fornix, 4 or 5 mm below the tarsal border at the level of the lower conjunctival vascular arcade.

Preseptal Approach

The preseptal approach permits access to the fat pads through the orbital septum and allows access to the orbital rim, retroorbicularis fat (ROOF), and the midface without any involvement of the orbicularis muscle or skin. The incision is made along the lower tarsal border, 1 or 2 mm below the lid margin. This incision extends through the conjunctiva lid retractors and capsulopalpebral fascia. The space behind the orbicularis is then entered, and the dissection is continued deep to the orbicularis but anterior to the orbital septum. This dissection is continued down to the orbital rim, and the arcus marginalis is easily released, affording access to the midface. Access to the fat requires resection or incision of the orbital septum.

Preoperative Planning

The best candidates for transconjunctival fat removal or redraping are those with excess fat and little if any real skin excess. The combination of transconjunctival fat removal and skin-pinch excision is a suitable procedure in some patients. Fat redraping is appropriate for patients with aging of the lid-cheek junction with little or no real skin excess.

Markings

With gentle pressure on the globe, the skin is marked directly over each bulging compartment. If fat redraping is planned, the nasojugal groove and lid-cheek junction are marked.

Operative Technique

The ideal candidate for the postseptal approach is a patient with bulging lower lid fat compartments with no real excess skin. The ideal candidate for the preseptal approach has aging of the lid-cheek junction with no real skin excess.

Anesthesia

The choice of local versus general anesthetic is the same as described previously for the upper eyelid.

Postseptal Approach: Incisions

The globe is protected with a corneal protector. Stay sutures of 5-0 Prolene are placed medially and laterally through the conjunctiva of the inferior fornix. These two sutures are then pulled upward, facilitating the dissection and also affording extra protection to the globe. A Blair retractor or traction sutures are then placed in the lower lid margin.

Lower Arcade

The incisions are made with the electrocautery, 4 to 5 mm below the lid margin at the level of the lower arcade.

I prefer to make two separate conjunctival incisions: one medially over the medial fat compartment and the second laterally over the central and lateral compartments. These two incisions leave an intervening bridge of conjunctiva over the inferior oblique muscle in an effort to minimize the risk of injury to the muscle during fat removal. A single continuous incision affords better exposure without significantly increasing the risk of muscle injury.

Once the conjunctiva and the adherent lower lid retractors and capsulopalpebral fascia have been incised, the fat compartments may not always be readily visible.

If the fat is not readily visible, gentle spreading with fine, blunt-tipped scissors will easily expose the fat. The central and lateral fat compartments are more easily identified than the medial fat compartment. I have found that resection of the central fat facilitates identification of the medial fat. It should be kept in mind that the inferior oblique muscle separates the central and medial fat pockets, whereas the arcuate expansion of the inferior oblique muscle separates the central and lateral compartments.

Once the fat is exposed, I like to deliver the fat through the incisions to assess the amount to be resected.

The exposed fat is then removed in a careful, graded fashion with the coagulator and Colorado tip needle. The endpoint is reached when the remaining fat is flush with the infraorbital rim when gentle pressure is applied on the globe.

Closure

No closure is required if two separate incisions are made. If a single, continuous incision is made, the wound is sutured.

Preseptal Approach: Incisions

One continuous, long incision is made just below the tarsal border. This is facilitated by retracting the tarsal plate upward and inferiorly with Blair retractors or through the placement of stay sutures in the lid margin. The incision is made with the electrocautery and a Colorado tip needle.

Once the incision has been made, stay sutures are placed along the inferior margin to facilitate exposure. The dissection is continued through the conjunctiva and lower lid retractors, exposing the orbital septum on the deep surface and the orbicularis on the superficial side of the incision. A Desmarres retractor is then placed deep to the orbicularis and pulled downward.

Exposure and Redistribution of Fat

Dissection is continued deep to the orbicularis but superficial to the orbital septum, downward toward the orbital rim. The arcus marginalis is released, and dissection may continue into the midface as needed. The orbital septum is then opened and the fat compartments exposed, trimmed if necessary, and then the fat is mobilized over the orbital rim.

Retention of this fat over the rim is achieved through transcutaneous sutures. My preference is 6-0 catgut, tied over a small pledget of Xeroform if needed. The suture is introduced through the lower lid skin at the lid-cheek junction according to the preoperative markings.

The suture traverses the skin and orbicularis muscle.

It is then placed through the mobilized periorbital fat below and then back through the orbicularis and skin.

Several sutures are placed and tied over the pledgets if needed, once the last suture has been placed. The conjunctival incision is then closed with an intraconjunctival suture so that there will be no exposed sutures that could irritate the cornea.

Postoperative Care

The patient's head is elevated, and ice packs are placed on the eyelids.

Results

This young woman in her early thirties underwent transconjunctival removal of fat from the lower eyelids. The dark circles were ameliorated by the application of hydroxyquinone skin bleach. Her postoperative result is shown several months after the procedure.

Transconjunctival fat removal with erbium laser resurfacing was performed on the lower eyelids of this young woman in her forties. She is shown 1 year and 3 years postoperatively. She demonstrates an average to below average result because the aging of the lid-cheek junction has not been addressed through the transconjunctival removal of fat from the lower eyelid. An alternative approach would have been pre-septal conjunctival fat redraping over the lower lid-cheek junction.

This 70-year-old man requested improvement of the fat bags in the lower eyelid. He wanted a simple procedure with minimal recovery. Transconjunctival postseptal removal of fat from the lower lid was done. The result shown several months later demonstrates satisfactory reduction of the fat bags, although the aging of the lower lid–cheek junction and aging skin have not been addressed.

Outcomes

The transconjunctival approach to upper and lower eyelid blepharoplasty has been relatively trouble free. Complications involving exposure and lid retraction are extremely rare. Recovery is rapid with little risk of chemosis. Postoperative swelling is minimal compared to transcutaneous approaches.

Injuries to the levator aponeurosis in the upper eyelid resulting in ptosis have not been reported. Although injury to the inferior oblique muscle during transconjunctival lower lid blepharoplasty has been reported, it is very rare, and I have not personally encountered it. Although the muscle is always at risk when resecting fat from the central and medial pockets, I do not think that this risk increases with the transconjunctival approach.

Concluding Thoughts

The transconjunctival approach remains a safe and effective method for eyelid recontouring, lid-cheek blending, and periorbital rejuvenation. The approach offers little in the way of orbicularis muscle reshaping, skin removal, or lid anchoring. Modifications such as the skin pinch and approaching the orbicularis and canthus through the upper eyelid have been described, thus extending the indications for this approach.

Clinical Caveats

Upper Lid

Only the nasal fat pocket can be approached through the conjunctiva.

Lateral extension of the conjunctival incision should be avoided because it may damage the levator aponeurosis.

Ideal candidates are individuals with fat herniation of the nasal fat pocket with no real skin excess.

Lower Lid

The preseptal approach allows fat excision, fat redistribution, and access to the midface.

A postseptal approach allows fat removal only.

The inferior oblique muscle separates the medial and central fat compartments.

A preseptal approach with fat redistribution is technically challenging.

Ideal candidates have excess fat with no real excess skin.

Annotated Bibliography

Pacella SJ, Nahai FR, Nahai F. Transconjunctival blepharoplasty for upper and lower eyelids. *Plast Reconstr Surg* 125:384-392, 2010.

The authors review this technique, including anatomy, indications, and surgical approaches. They conclude that this remains a safe and effective technique for the treatment of periorbital aging.

Upper Lid

Guerra AB, Metzinger SE, Black EB. Transconjunctival upper blepharoplasty: a safe and effective addition to facial rejuvenation techniques. *Ann Plast Surg* 48:528-533, 2002.

The authors performed 42 bilateral transconjunctival upper blepharoplasties in patients undergoing facial and eyelid rejuvenation. They introduced the term “bare area.” The CO₂ laser was used concomitantly for treating fine rhytids and tightening loose upper eyelid skin. They found the procedure to be an effective method for removing medial upper eyelid fat with minimal complications.

Januszkiewicz JS, Nahai F. Transconjunctival upper blepharoplasty. *Plast Reconstr Surg* 103:1015-1018; discussion 1019, 1999.

This is our original description of the transconjunctival approach for removal of excess fat in the medial pocket of the upper eyelid. We reported that this was safe and effica-

cious as a primary or secondary procedure. Our initial experience in 20 patients (5 primary and 15 secondary) revealed the following: no complications, no revisions, and the patients were uniformly pleased with their results.

Goldberg RA. Transconjunctival orbital fat repositioning: transposition of orbital fat pedicles into a subperiosteal pocket. *Plast Reconstr Surg* 105:743-748; discussion 749-751, 2000.

Rejuvenation of the lower eyelid complex is based on the principle that the contour changes that characterize aging involve not only prolapse of orbital fat but also descent of the cheek tissues, resulting in accentuation of the orbital rim and tear-trough groove. When a deep groove is present along the orbital rim in the area of the tear-trough deformity, it is advantageous, rather than removing orbital fat, to reposition the fat over the orbital rim through the opened arcus marginalis onto the superior face of the maxilla. The author describes orbital fat repositioning through a transconjunctival approach and follows 24 patients after orbital fat repositioning. It was found that although the fat pedicle undergoes some variable resorption, the viability of the graft, the texture and contour of the repositioned fat after a healing period of 1 to 2 months, and the excellent patient acceptance are indicative of the viability of orbital fat repositioning.

Jones GE, Trimble-Bried J, Nahai F. Transconjunctival blepharoplasty: a clinical experience. In *Perspectives in Plastic Surgery*. St Louis: Quality Medical Publishing, 1995.

This article describes our technique for transconjunctival fat removal and a comparison of complications with the transcutaneous approach. The overall complication rate was 5.3% with the transconjunctival approach and 12.7% with the transcutaneous approach. Exposure problems and lid retraction were 0% with the transconjunctival approach and 7% with the transcutaneous approach.

McCord CD, Shore JW. Avoidance of complications in lower lid blepharoplasty. *Ophthalmology* 90:1039-1046, 1983.

In an article devoted to avoidance of lower lid malposition, the authors describe the tightening of the tarsoligamentous sling in combination with a lower lid blepharoplasty. As an alternative method, they also describe postseptal fat removal from the lower eyelid. They describe this as "the fornix removal of fatty pads from the lower eyelid—the 'behind-the-lid' blepharoplasty." This alternative method significantly reduced or even eliminated the risk of lid retraction. They recommend this method for patients with excess fat in the lower eyelid and tight skin.

Zarem H, Resnick JI. Expanded applications for transconjunctival lower lid blepharoplasty. *Plast Reconstr Surg* 88:215-220, 1991.

Initial reports on the transconjunctival approach for lower lid blepharoplasty have focused on the young patient with isolated fat prominence. The authors describe their experience with transconjunctival lower lid blepharoplasty. They also discuss indications, which were expanded to include patients with apparent skin excess, and outcomes.

CHAPTER 32

Lower Eyelid Pinch Blepharoplasty

LORNE K. ROSENFELD

The lower eyelid blepharoplasty embodies a classic surgical paradox worth revisiting: the more one performs a particular surgery, the more respect it may command. Whereas ignorance may be bliss, knowledge can be quite motivating. Any surgeon who has critically assessed his or her skin-muscle flap lower blepharoplasty results would heartily agree with this statement.

When I examined my own results, I observed, not as infrequently as I would have liked, two particular stigmata of a less than perfect result at the lower eyelid. First, lasting mild scleral show was evident, often preceded by weeks of overly optimistic eyelid taping. This 55-year-old woman, shown preoperatively and 1 year after a traditional skin-muscle lower blepharoplasty, exhibits this telltale postoperative sign of scleral show.

Second, residual crêpey skin was identified, most often after treatment of prodigious fat herniation. This 48-year-old woman, shown preoperatively and 1 year after a traditional blepharoplasty, exhibits this “untreated” redundant skin.

I was compelled by these discomfiting observations to seek an effective solution—a modified procedure that would at once ensure optimal correction of the eyelid deformities and yet maintain normal eyelid posture. And so was born the pinch blepharoplasty series. My personal experience, reported in 2005, confirmed the safety and efficacy of this approach.

Although the true incidence of eyelid malposition after a traditional muscle flap blepharoplasty is not well defined, the plethora of articles on the subject attests to its persistence. Scleral show has been ascribed to multiple causes: excess skin removal, untreated eyelid laxity, denervation of the orbicularis muscle, and scarring of the outer or middle lid lamellae. This postoperative problem may be considered subtle and indeed is often not even acknowledged, but it represents what could also be seen as a glaring example of the “operated” look that we should all strive to avoid. As for the excess skin left behind postoperatively, this problem has been equally neglected in the literature.

Evolution of Technique

There have been many efforts to reduce the incidence of eyelid malposition following traditional blepharoplasty. As documented by Zarem and Resnick, one approach has been to forego the skin incision entirely, thus preserving the integrity of the outer and middle eyelid lamellae, and to approach the eyelid instead through the conjunctiva only. Although the incidence of scleral show may be less with this approach, there can be a greater chance of untreated excess eyelid skin.

In another effort to avoid the skin incision and still treat the skin, skin resurfacing with a chemical peel or laser, in conjunction with a transconjunctival approach, can indeed reduce the incidence of scleral show. However, unless the skin redundancy is modest and the entire face is treated, resurfacing may not adequately treat the skin redundancy and can otherwise produce distracting lines of demarcation. Additionally, if these therapies penetrate too deeply, undesirable changes in eyelid posture may still occur.

With a skin-muscle flap, a relatively conservative resection of the skin has always been advocated, regardless of the extent of redundancy. Indeed, it is often impressive how little skin is actually removed despite such an aggressive flap dissection. And of course, in a patient with more significant excess skin, this conservatism has surely led to inadequate treatment.

Another adjunctive technique to a blepharoplasty is the canthopexy, particularly in a patient with a lax eyelid. There is no question that this repair helps reduce the incidence of lid malposition, but the results have been frustratingly inconsistent. We have all seen scleral show after a traditional blepharoplasty despite the addition of a canthopexy, even when applied prophylactically. An inadequate canthopexy, coupled with overaggressive skin resection, and the inciting factors of muscle denervation and middle lamellar scarring, probably explain this inconsistency. The deliberate preservation of a wider orbicularis strip of muscle, when conducting a skin-muscle flap approach, may be salutary but has clearly not proved to be the complete answer.

The idea of pinching the excess skin from the lower eyelid is not a new one; in 1973 Parkes et al were the first to suggest the technique. This description, which predated the transconjunctival approach, attenuated its potential benefits by also describing the division of the underlying orbicularis muscle to retrieve the excess fat.

Then in 1992 Dinner et al published a case report on the ultimate combination of the skin pinch with the transconjunctival approach in a “no flap” technique. Ristow, in 1994 in Mimis Cohen’s textbook, included the concept of a direct skin resection with a measured and marked resection.

My impetus to revisit and refine a pinch blepharoplasty came from a personal communication with Glenn Jelks in 2000. The solution became even more lucid when our decades-old standard approach to the upper eyelid blepharoplasty was considered: we “pinch” the eyelid excess to determine the extent of the excision while observing the effect on the eyelash and brow posture. Why not apply the same simple metric to the lower eyelid? So was born the “pinch blepharoplasty” series.

Advantages

My personal experience of more than 400 pinch blepharoplasties confirms that this approach is indeed capable of producing better, more consistent results than the traditional skin-muscle flap technique. This variation offers two distinctive advantages: more crêpey skin can be safely removed, and an aesthetic eyelid posture is secured.

This rewarding marriage of goals is primarily the result of the inherent accuracy of the pinch technique. The approach enables the surgeon to assess and define in real time the prospective skin resection as well as carefully evaluate its effect on eyelid posture. The pinch technique avoids a heavy skin-muscle flap, which can otherwise create both worrisome vertical traction and more swelling. Additionally, the pinch blepharoplasty eliminates the usual violation of the orbicularis muscle and orbital septum, an action that could lead to denervation, scarring, and poor eyelid posture.

Another possible reason for the improved results is the often seen amelioration of the eyelid-cheek groove with a more youthful vertical shortening of the eyelid, perhaps secondary to the effacing effect of the significant skin resection.

These benefits translate into a more adaptable and consistent blepharoplasty. This advantage is seen particularly and most gratifyingly in morphologically challenging patients with a negative vector and poor lid posture; older patients with poor lid tone; patients with extensive skin or festoons; and younger patients with primary

skin redundancy and nominal excess fat. If there is asymmetrical skin between the eyelids, or even within one eyelid itself, the pinch can be tailored accordingly. Empowered with this versatile tool, the surgeon can now treat the medial eyelid skin, a zone that was traditionally neglected, for an even more complete result. In addition, because the skin excess is more thoroughly treated, the surgeon can avoid the need for regional laser resurfacing of the eyelid, with its added period of healing and attendant, often distracting lines of demarcation.

The advantages of the pinch blepharoplasty can be doubled with a staged reapplication of the pinch to excise even more skin. This “repinch” can be accomplished quite simply, with a local anesthetic. Thus it is feasible that essentially all crêpey skin at the lower eyelid can now be removed.

Indications and Contraindications

The pinch lower blepharoplasty can comfortably usurp the standard skin-muscle flap technique. Therefore this approach may be offered to the same group of patients. In contradistinction to the standard technique, there is a productive breadth of application, depending on the extent of the patient’s problem. That is, all patients are candidates, but some are better candidates than others. Although results will be superior in all patients, defining the best and worst patient candidates for the pinch most effectively illustrates the nuances of the technique.

The ideal patient has abundant thin, crêpey skin, minimal excess fat, and morphologically advantageous anatomy (such as high cheekbones and almond-shaped eyes). With the application of the pinch and a planned second pinch procedure, if necessary, the improvement achieved in these patients can be dramatic, simply because the surgeon is able to more fully treat the eyelid.

At the opposing end of the spectrum, the imperfect patient is one with thicker, sun-damaged skin, which clearly will not “pinch” well. In these patients, it is best to plan the surgery so that the skin will have the least distortion from local anesthetic and to apply the pinch conservatively. Just as with patients with very thin skin, a thick-skinned patient will equally benefit from a staged second pinch procedure.

Because a dramatic skin resection can be done with this approach, the surgeon must be cautious when applying the pinch to a patient with equally significant redundant fat, because some of this skin must remain to redrape the now less convex lower eyelid. Again, these patients can always undergo a simple second pinch procedure at a later date.

Pertinent Anatomy

The essence of the pinch technique embodies a key anatomic principle: to violate the eyelid anatomy as little as possible, and if it is compromised by age or genetics, to repair it. Between the transconjunctival approach and the pinch, the pinch touches and takes only what it needs to—the skin—leaving behind the critical neuromechanical support: the orbital septum and the orbicularis muscle and its attendant nerves.

As for the canthopexy, the key anatomic principle is to keep it simple. Because the lateral canthus truly comprises several components and is not easily identified as a distinct structure, the canthopexy has to become a kind of maneuver “on faith”: you can only really feel its presence. That is, rather than trying to dissect and visualize the canthal tissues themselves, the surgeon need only grasp and pull whatever tissue is present in the area to know the “right stuff” has been captured. Then it simply becomes a matter of manipulating this anchor thoughtfully to perform an individualized canthopexy.

Preoperative Assessment

History

There are several critical historical points to be gleaned, including a history of eye dryness, tearing, or the need for drops; allergies; Graves' disease; prior eyelid surgery; and previous injection of tissue fillers.

Physical Examination

The preoperative physical examination should include the same components as for any blepharoplasty. However, the difference is that because the pinch allows one to modify the surgery to match the patient's problem, the value of a detailed analysis is even more rewarding.

The critical elements to evaluate are listed in the box.

Critical Factors to Assess in the Physical Examination

The extent of the redundant skin: If necessary, a second pinch procedure can be planned in advance. This is particularly relevant in a patient with significant "active" skin: exaggerated wrinkling on animation.

The extent of the redundant fat: Depending on the volume of excess, more or less skin should be pinched to ensure that enough skin is left behind.

The degree of lid laxity and attendant scleral show (as evaluated by a snap test): This can be treated efficiently with a stitch canthopexy.

The level of the lateral canthus (canthal tilt): The canthal position can be adjusted relatively precisely with a stitch canthopexy.

The vector angle of the globe to the malar (positive/neutral/negative): This aids the surgeon in the design of the best application of the pinch and canthopexy components of the surgery.

Photography

There are several tenets to be followed for photographic evaluation of the eyelids and documentation of the results.

Prevent Parallax Error

Parallax refers to the apparent displacement or difference in the apparent position of an object viewed along two different lines of sight, such as occurs because the lens of a camera and the viewfinder see the subject from a slightly different position. Thus photographs must be taken with the patient and surgeon seeing “eye to eye”; that is, there should be no height discrepancy that could distort the appearance of the posture of the lower eyelid in relation to the globe.

THE PARALLAX EFFECT

Patient tipped up

Patient tipped down

Patient level

Camera high

Camera low

Camera level

This problem can be manifested when either the patient is not level or the camera is not level. These effects can mask or exaggerate the actual eyelid position.

Beware of the Moro Reflex

Close-up with Moro

Full face without Moro

When a tighter photo of just the eyelids is to be taken, some patients, anticipating the flash's effect, may widen their eyes dramatically. If this is noted, pulling the camera back to include a full-face picture should correct the distortion.

Follow the Dermatologist's Credo

Close-up preoperative photo

Close-up postoperative photo

To accurately document the effects of the pinch procedure, progressively closer pictures of the face should be taken, from full face to just wrinkles at the lower eyelid.

Control the Patient's Emotions

There is a place for both active and passive photographs of a patient's lower eyelid. Photos should be taken of the patient smiling to define the extent of muscle-skin excess.

Patient smiling preoperatively

Patient smiling postoperatively

Often orbicularis wrinkling is the patient's primary concern, and any correction of this problem is a true measure of a technique's efficacy.

Patient's smile hides scleral show

Patient at rest with scleral show

On the other hand, a smile can camouflage an eyelid posture or a scleral show problem.

Compare the Present With the Past

The patient should be asked to bring photographs from the past (such as college or wedding photos or well-focused candid photos). The insight gained from reviewing such historic images is invaluable not only for observing changes in the characteristics of the periorbital area but also in our attempt to recapture the patient's characteristic expression or persona.

Patient Education

A patient with significant wrinkling must be informed that a second pinch blepharoplasty should be considered, depending on the salutary effects of the first procedure. The goals and actions of a canthopexy should be explained, because the palpebral fissure will become more almond shaped.

Planning and Technique

Particularly when first attempted, the pinch procedure is best conducted with infiltration of as little local anesthetic as possible. With deeper sedation or general anesthesia, it is both possible and ideal to use no local infiltration. This consideration is critical, because it allows the surgeon to most accurately judge and pinch the skin excess without the potential distortion caused by aggressive local infiltration.

32-1 Pinch
blepharoplasty

Surgical Plan

1. If a local anesthetic must be used, place it in the lower eyelid in the region of the future pinch.
2. Conduct the upper eyelid blepharoplasty, leaving the wound open.
3. Complete the transconjunctival portion of the lower blepharoplasty.
4. Perform a stitch canthopexy through the upper-outer eyelid wound.
5. Close the upper eyelid wound.
6. Perform the lower eyelid pinch procedure and close the wound.

Marking

The first step is to mark a guiding “pinch line” along the lower eyelid, representing the *uppermost* margin of the future excision. Medially, this line is usually placed within a few millimeters of the ciliary margin, continuing in a straight line laterally, deliberately leaving a progressively enlarging triangular island of intact skin of 4 to 5 mm in minimum height below the lateral eyelid margin. This maneuver further discourages scleral show by lessening the purse-string–like scar contracture that may occur with a curvilinear incision hugging the ciliary margin. However, the latitude of this line can be modified, depending on the location and quality of the excess skin. That is, the pinch line can be moved up or down on the eyelid to facilitate maximal skin removal. If the skin is noticeably thicker, the pinch line should be moved farther away from the ciliary margin to help prevent scleral show.

Sequencing of Procedures

The sequence of operative steps is critical. If an upper blepharoplasty is planned as well, it should be conducted first, with wound closure delayed until after a canthopexy but before the lower eyelid pinch. Thus the lateral upper eyelid wound is available for the canthopexy, and any lower eyelid skin redundancy that may be treated with closure of the upper eyelid takes place before the pinch procedure. On the other hand, if only a lower blepharoplasty is to be performed, to accomplish a pexy a 10 to 15 mm counterincision may be made in the lateral upper eyelid along the path of an upper blepharoplasty.

Operative Technique

After the markings, the surgeon applies any local anesthetic early and judiciously to minimize the amount of local swelling and maximize its resolution. The transconjunctival portion of the procedure is best conducted preceding a possible canthopexy, lest the surgeon have difficulty distracting or even undoing the tightened eyelid. The canthopexy should be performed before the lower eyelid pinch procedure, because the potential lateral lift of the pexy can treat some of the lower eyelid excess. As for the lower eyelid, the excess fat is trimmed as indicated and the wound reapproximated at its midsection with a 6-0 fast-absorbing catgut suture.

The upper eyelid portion of the blepharoplasty is then performed as premarked. The excess skin and as indicated, excess muscle, are resected. Then the underlying orbital fat is treated, if necessary, with electrocautery and/or excision. Before closure of the upper eyelid wound, the lateral stitch canthopexy is performed.

I distinguish two kinds of canthopexy to consider and design: prophylactic and therapeutic. The choice is primarily determined by two factors: the position of the lateral canthus and the posture and tone of the lateral lower eyelid. If the lateral canthus is at or above the horizon and/or the lower eyelid tone is mildly weak without scleral show, a prophylactic pexy is in order. If instead the lateral canthus is below the horizon and/or the lower lateral eyelid tone is weak with scleral show, a therapeutic lateral canthopexy should be performed. Clearly, there is always a gray zone in this arbitrary categorization: there are patients with a normal neutral canthal cant who could have an aesthetic improvement with a slight elevation of the lateral canthus, and as such the canthopexy could be considered not only prophylactic but therapeutic as well. This nuance is particularly relevant in a patient who in youth had an almond-shaped eye.

In either case, the procedure is conducted through the lateral aspect of an upper blepharoplasty incision. First, using the Bovie, a segment of approximately 1 cm of the superolateral inner orbital rim is exposed, with great care to preserve the integrity of the periosteum.

Then a subfascial/submuscular “tunnel” is created between the orbital rim and the lateral canthus using round-tipped iris scissors.

A very fine, curved mosquito clamp is passed down the tunnel, and its very tip is used to capture the lateral canthal tissue.

If a prophylactic canthopexy is planned, the mosquito clamp tip is passed up to the orbital rim to determine the ideal pexy location, which will at once modestly tighten the lower eyelid and maintain the canthal angle. If a therapeutic pexy is desired, the

mosquito clamp is manipulated as needed to produce the desired correction of the eyelid posture and/or canthal position. If necessary, the canthal tissues, still within the grasp of the mosquito, can be gradually released with a scissors or Bovie. This maneuver should be conducted with the mosquito on tension so that the surgeon can proprioceptively conduct adequate liberation of the canthus. At most, a partial release is all that is necessary to properly treat the majority of eyelids and thwart overcorrection.

The canthopexy is sutured in place by taking a double bite of the captured canthal tissue with a 5-0 clear nylon suture and securing this tissue to the periosteum within the orbital rim. The canthopexy is shown before and after it is secured. If desired, transparent scleral protectors may be used, or those shown may be removed, to facilitate placement of the pexy stitch.

The surgeon can evaluate the efficacy of the pexy on eyelid tone by conducting an immediate distraction test. An intraoperative distraction test is shown before and after the canthopexy. The canthal position can also be assessed by sitting the patient upright. NOTE: The suture should be reapplied if the desired lid tightening or canthal positioning effect has either not been achieved or is exaggerated.

Pinch Blepharoplasty

Then, using a pair of fine Adson-Brown forceps, the subciliary skin is progressively pinched along the premarked line into a standing “wall” of skin. The endpoint should be the maximal effacement of wrinkled skin resting primarily *below* while preserving a normal posture of the eyelid margin *above*.

With a forceps producing linear traction and a straight pair of scissors, the wall is amputated at its base.

The appropriate amount of skin has been removed if the wound edges are close to each other or just kissing. The wound may be opened to electrocoagulate any small bleeding vessels and is then closed with a 7-0 running nylon suture. No taping or other support of the eyelids is necessary.

Postoperative Care

Patients are started on iced cotton eye soaks during the surgery itself. If the eyes are iced meticulously, there will be less swelling and bruising. The patient performs this same icing routine continually for the first 48 hours, with intermittent breaks to avoid anxiety. Thereafter, icing can be used for comfort as needed.

As an additional proactive effort to encourage faster healing, patients undergo in-office ultrasonic therapy and lymphatic massage within the first postoperative day or two. This is continued for two more sessions over the subsequent week or so. This modality is a natural adjunct to the pinch blepharoplasty's goal of a faster recovery. In addition, herbs (*Arnica montana* and bromelain) to reduce bruising and swelling are given for the first 2 weeks postoperatively. Stitches are removed at 5 days, and no supportive tape is applied. At 2 weeks after surgery, the patient may gradually return to routine exercise over the subsequent 4 weeks.

At 6 months or more after the initial procedure, a planned repinch may be performed. It is usually performed with a local anesthetic and the addition of diazepam (Valium) as necessary. If the patient has lost some of the effect of the first canthopexy or still has a significant amount of redundant skin, planning a repeat canthopexy is prudent.

Problems and Complications

The gratifying essence of the pinch technique is that its entire premise is built on the goal of preventing the routine problems and complications seen with the traditional approach. Thus scleral show and residual eyelid wrinkling are very rare occurrences. However, some issues unique to the pinch blepharoplasty should be noted. If a non-absorbable nylon-type suture is used for the canthopexy, its knot can sometimes be seen postoperatively in a very thin-skinned patient and may need to be clipped. If the pinch is electively performed slightly lower on the eyelid, where the wrinkles often rest, the scar may initially be more visible; however, these scars do uniformly mature inconspicuously. In a patient with a significant amount of excess skin who specifically asks for or prefers a scar aligned with the eyelash, they should be informed of the reduction in wrinkle removal that may result.

When conducting the canthopexy, if there is excessive manipulation of the tissues, a chemosis covering the lateral white triangle of the globe may result. This problem is usually self-limiting but should be supported with lubricating or medicinal eye-drops. To obviate this nuisance effect, it is best to deliberately capture the pexy material with your first bite.

Finally, if performed too aggressively, the canthopexy will produce an overly corrected result. Usually the effect will improve over time. On the other hand, if the pexy is not harnessed adequately, the patient may be left with a canthal or lid deformity. The best preventive maneuver is to critically assess and redo the pexy if necessary in the first place.

Outcomes

The spirit of this modification of the lower blepharoplasty is defined by a triad of maneuvers: (1) the deliberate preservation of the eyelid's integrity with a transconjunctival incision, (2) the mindful alignment of the lower eyelid with respect to the globe and canthus with the application of the canthopexy, and, pivotally, (3) the proficient excision of the redundant skin with the mastery of the pinch technique.

These examples demonstrate the extent of skin excision possible with pinch technique, averaging 8 to 12 mm. In addition, the patient usually has less bruising and swelling and heals more rapidly.

The typical early appearance of a postoperative patient is shown at 5 days and at 7 days. Together these efforts consistently deliver a salutary removal of redundant skin of the eyelid while still safeguarding its posture. In fact, with greater comfort performing the stitch canthopexy, the surgeon can often go one step further and cre-

ate a subtle, more aesthetic shape to the otherwise normal lower eyelid. On the other hand, particularly in a morphologically challenging patient, the canthopexy may definitively correct the attendant canthal deformity. Additionally, the application of the repinch procedure, best planned for before the first pinch is performed, has reliably contributed to even more satisfying results.

Results

The following cases were chosen to demonstrate the power of the pinch procedure given various patient presentations—from the best to the more difficult blepharoplasty candidates.

The Older Patient

This 68-year-old woman is shown preoperatively and 1 year after an upper and lower pinch blepharoplasty. Lower eyelid aging was corrected and a normal eyelid posture was ensured.

This 53-year-old woman with the classic stigmata of aging would previously have undergone a routine blepharoplasty with CO₂ laser or chemical resurfacing. Instead, upper and lower pinch blepharoplasties with prophylactic canthopexies were performed. She is seen preoperatively at age 53, in a historic photo at age 23, and postoperatively at age 54, with an attractive, youthful eyelid posture restored.

The Younger Patient

This 36-year-old patient presented with modest wrinkling. She underwent only a lower pinch blepharoplasty with full correction, as seen 2 years postoperatively, obviating the need for laser or other resurfacing intervention.

Orbital Groove

This 42-year-old woman, who requested upper and lower blepharoplasty, demonstrated significant asymmetrical excess of both fat and skin. The pinch blepharoplasty allowed an equally asymmetrical excision and a salutary effacing of the deep orbital groove, as seen 14 months postoperatively.

Problem: Anatomy

This 45-year-old patient had morphologically challenging anatomy: a triad of a large globe, a negative orbital vector, and lateral canthal cant (*left and center*). In addition to an upper blepharoplasty, she underwent a therapeutic canthopexy and pinch lower blepharoplasty that corrected both the depressed canthus and the eyelid problem itself, as shown 18 months postoperatively (*right*).

Problem: Anatomy

This 58-year-old patient had a spectrum of poor “design” issues: negative cheek and lateral canthus angles and scleral show. He is seen 16 months after upper and lower blepharoplasties with pinch and therapeutic canthopexies (*right*).

This 63-year-old patient had poor morphology and significant, albeit asymmetric redundancy at the lower eyelids, and proper scleral show. He underwent an upper and aggressive lower pinch blepharoplasty with an asymmetrical canthopexy. He is shown preoperatively and (*below*) with results at 7 days and at 6 months.

Problem: Redundant Skin

This 52-year-old woman had considerable excess crêpey skin. Two years after an upper and lower pinch blepharoplasty, she demonstrates essentially complete removal of the redundant skin; good eyelid posture has been maintained.

This 73-year-old woman was an ideal patient for a pinch blepharoplasty. The photo series reveals the pathway to relatively complete repair of lower eyelid aging. The patient is shown intraoperatively, demonstrating the prodigious pinched wall of skin and wound, with preservation of an attractive eyelid posture. The 1-year postoperative view confirms the rewarding improvement.

Problem: Persistent Skin Excess Requiring a Repinch Procedure

Preoperative

6 months after first blepharoplasty with canthopexy

This 56-year-old patient presented with advanced sun-damaged skin at the eyelids, so a second pinch procedure was planned. She underwent an upper and maximal lower pinch blepharoplasty with canthopexy. At 6 months postoperatively she demonstrated persistent excess in the upper and lower eyelids.

A revision was performed, with reexcision at the upper and repinch at the lower eyelids. The repinch roll and extent of repinch wound at approximately 10 mm are shown.

At age 20

1 year after repinch procedure

The patient is seen in a historic photo at age 20 and 1 year after the repinch surgery, demonstrating reasonable success at recapturing her youthful look.

Repinch Procedure

This 72-year-old woman illustrates the power of the repinch procedure. The staged surgery was performed at approximately 6 months. The patient is shown preoperatively and 6 months after the first pinch procedure.

The intraoperative views demonstrate the second pinch roll, the wound kissing, and the pinch wound.

The patient is shown 4 days after the second pinch procedure and 1 year later.

This 68-year-old patient is seen in close-up views of progressive correction: preoperatively, following the first pinch blepharoplasty, and following the repinch surgery, each result 6 months apart.

Concluding Thoughts

One could say that these modifications empower the surgeon to tame and command greater control of the lower eyelid. Personally, I have found the effects of this technique quite gratifying: I have both a newfound serenity when approaching the lower eyelid with this more reliable means for preventing surgical stigmata and a satisfaction with the results because of the more comprehensive eyelid correction that can be realized.

The procedure's advantages are particularly manifested when one is confronted by challenging morphology. As an endorsement of the efficacy of the pinch blepharoplasty, I have not performed a skin-muscle flap lower blepharoplasty in more than 12 years. The pinch blepharoplasty has eliminated the need for lower eyelid resurfacing in most cases.

In addition, we have abolished the proverbial “therapeutic” postoperative taping. I now perform more canthopexies intelligently and excise more skin confidently. The results of these efforts have included consistently faster patient recovery, more accurate canthal and eyelid positioning, and what is most important, significantly improved aesthetic outcomes.

Clinical Caveats

The surgeon should infiltrate the local anesthetic as early and minimally as possible. The less distortion of the tissues, the more accurate and facile the pinch maneuver will be. This is particularly germane at the start of a surgeon's learning curve. To this end, it is often helpful to sedate the patient more deeply just before the pinch procedure.

The addition of a stitch canthopexy is a preoperative decision predicated on evaluation of both the position of the lateral canthus and the posture and tone of the lower eyelid. The action of the canthopexy may be classified as either prophylactic (elderly, prominent globe, malar hypoplasia, or "negative" lateral canthal position) or therapeutic (laxity or scleral show).

Generally, if a patient is deemed to be a candidate for a lower blepharoplasty, at least a prophylactic canthopexy should probably be performed. Thus almost every patient now undergoes a canthopexy. In effect, the stitch canthopexy, when judiciously harnessed, empowers the surgeon to take full advantage of the pinch procedure and perform the most complete removal of redundant skin.

Both the pinch blepharoplasty and the stitch canthopexy techniques have a notable learning curve. During this evolution, the surgeon should be aware that it is deceptively easy to "overpinch" or "overpexy." As a layer of protection initially, it is prudent to pinch a few millimeters farther away from the lash margin compared with the traditional incision. This scar consistently heals imperceptibly. Also, when conducting a stitch canthopexy, the surgeon should have a low threshold for replacing the stitch if an overcorrection is perceived; it may not "settle" enough on its own postoperatively. Likewise, the pexy should be reattempted if an undercorrection is noted.

The pinch portion of this technique can easily be repeated with the patient under local anesthesia to treat any residual crêpey skin.

CHAPTER 33

Ptosis Surgery in the Blepharoplasty Patient

CLINTON D. MCCORD, JR., FOAD NAHAI

Eyelid ptosis, or abnormal drooping of the eyelid, is a condition frequently encountered during aesthetic and reconstructive eyelid surgery. Failure to identify this problem preoperatively or to incorporate correction of this condition into the operative plan will compromise the ultimate result. This chapter focuses on adult ptosis resulting from acquired dehiscence of the levator aponeurosis and the type of levator surgery that is most effective for a patient seeking blepharoplasty. For this group of patients, the primary goal of surgical correction is on repair of the levator aponeurosis. Ptosis may be repaired alone or in combination with upper lid blepharoplasty. Although the correction of lid droopiness is the primary goal in ptosis surgery, other important related issues include eye protection and identification of any underlying pathologic process requiring diagnosis and treatment. Sudden-onset ptosis with neurologic signs of pupillary abnormalities and ocular motility should alert the surgeon to underlying neuromuscular problems, such as myasthenia gravis, Horner's syndrome, and third nerve paresis. A patient with these signs should undergo neurologic evaluation.

Pertinent Anatomy

Levator Dehiscence

Levator dehiscence is an abnormality or thinning and stretching in the levator aponeurosis that allows a downward movement of the tarsal plate. It may occur without any known predisposing cause or may occur following direct trauma, such as acute swelling from a bee sting or a "black eye." Levator dehiscence is known to occur following an ocular procedure, such as cataract surgery, and is thought to be exacerbated by wearing rigid gas-permeable contact lenses. Any significant edema can cause levator dehiscence in predisposed individuals. Levator muscle function and elasticity are normal in these patients, and there is no lagophthalmos in downgaze.

The characteristic clinical appearance of ptosis as the result of aponeurotic dehiscence is good to excellent levator function, a high lid crease, and thinning of the eyelid tissues above the tarsal plate. In some cases the high lid crease may be obscured by dermatochalasis.

These patients demonstrate various examples of levator dehiscence. The patient on the left has bilateral levator dehiscence, whereas the patient on the right demonstrates levator dehiscence following cataract surgery.

Landmarks of the Levator Complex

The three major attachments of the levator Müller's complex are illustrated in the schematic of upper eyelid anatomy. These attachments include:

1. Müller's muscle, inserting into the upper tarsal border
2. Aponeurosis attachments to the anterior tarsus, inserting into the lower third of the anterior tarsus
3. Additional extensions of the aponeurosis that penetrate the orbicularis muscle, inserting into the skin and creating the lid crease

In a patient with involutional ptosis, the anterior tarsal attachments of the aponeurosis are defective because of stretching and disinsertion, thus causing lengthening of the lid and ptosis. Some of the lid crease attachments of the aponeurosis tend to remain intact, and the persistent attachments to the skin cause the migration of the lid crease to a higher level. An additional anatomic change that occurs in patients with involutional ptosis is dehiscence of the medial horn, which causes a lateral displacement of the upper lid tarsal plate.

This cross section of the upper eyelid shows normal attachments of Müller's muscle and levator aponeurosis (*left*). Aponeurotic dehiscence with retraction of the lid crease is illustrated (*right*).

The accompanying dehiscence of the medial horn of the levator causes outward migration and a lateral shift of the tarsal plate so that the peak of the tarsal plate, which is normally centered above the pupil, is shifted temporally. If one performs surgery on the levator so that the maximum pull of suturing is at the peak curvature of the tarsal plate, the result will be consistent temporal overcorrections and "flare."

The levator is shown on frontal view. Normal structures and landmarks can be seen (*left*). The lateral shift of the tarsal plate as a result of dehiscence of the medial horn and supportive structures of the upper lid is demonstrated (*right*).

This woman with involutional ptosis is shown with markings placed on the eyelids in line with the peak curvature of the tarsal plate superiorly. With her eyes open, lateral displacement of the peak of the tarsal plate is evident as a result of release of the medial horn on the ptotic side.

Levator function is characteristically good to excellent in these patients. In some patients, however, ptosis may rarely be caused by levator weakening from fatty degeneration of the levator muscle rather than from aponeurotic thinning. This uncommon occurrence is thought to represent another subgroup within the etiologic factors of involutional ptosis. In many cases of acquired ptosis, diagnostic testing is needed to rule out neurologic or myopathic disease.

Preoperative Assessment

Obtaining a detailed medical history is essential. The surgeon should ask for a list of medications the patient takes, about any previous history of trauma, previous ocular surgery, instances of severe eyelid swelling, any bee, hornet, or wasp stings, or a family history of ptosis. Symptoms such as double vision or difficulty in swallowing should be evaluated. Old photographs of the patient sometimes reveal a ptosis that was not recognized at an earlier age, and this may be the only clue that the ptosis is congenital.

In the absence of any history or indicators in old photographs, the dynamic behavior of the lid may provide clues about the cause. If the lid is stiff, with lagophthalmos on downgaze in the ptotic eye, a congenital cause is very likely. However, levator muscles that have been scarred by trauma, inflammation, or previous surgery may also be stiff, and lagophthalmos in downgaze may be present in these patients and may make it difficult to establish the cause of ptosis.

Ptosis correction procedures always produce some postoperative stiffness of the upper lid. If the eye retains its moisture with an adequate tear film and good protective rotary eye movements are present, the patient should tolerate mild degrees of postoperative lagophthalmos. If there is impairment of eye protective mechanisms, exposure problems and conditions that threaten vision may develop. Each patient should be questioned about the presence of dry-eye symptoms and be examined for adequacy of tear film and evaluation of motility, including an assessment of Bell's phenomenon. Slit-lamp examination can show inadequacy of the precorneal tear meniscus. In patients with suspicious symptoms, a Schirmer's test with anesthesia should be performed. Additional deficiencies, such as decreased corneal sensation or facial nerve weakness, may further aggravate postoperative exposure. With the loss of one or more eye protective mechanisms, one should reconsider a surgical procedure or, at a minimum, the patient should be informed that a special lubricant might be necessary. If the patient's eyes are more intolerant of postoperative lagophthalmos, punctal plugs or actual reversal of the ptosis procedure may be necessary.

Almost all patients who wear contact lenses can be considered to have a normal tear meniscus and are safe candidates for ptosis surgery, because adequate tears are essential for wearing contacts. Postoperatively, soft lens wearers can resume routine wear of their contact lenses in 1 week. Patients who wear rigid gas permeable lenses must resume with a time buildup and are advised to get a special suction cup to assist with lens removal postoperatively. They can usually resume normal wear after a time but may need to modify the mechanics of their lens removal procedure.

A range of “normal” positions exists for the upper lid margin. Generally, iris color is visible above the upper pupillary edge. In cases of unilateral ptosis, the amount of ptosis relates to the position of the opposite normal eyelid. Subtle degrees of ptosis may be missed and unmasked by blepharoplasty if these landmarks are not observed, as can be seen in this patient, who, following upper lid blepharoplasty, maintained that her ptosis had resulted from the surgery. However, a comparison of the preoperative and postoperative photographs clearly demonstrates the presence of ptosis before surgery, and the condition was subsequently “unmasked” by the surgery.

Levator Function

Upper lid excursion, from extreme downward gaze to extreme upward gaze with the eyebrow firmly splinted, is the accepted method of measurement of levator function. This is measured in millimeters by placing a rule vertically in front of the eyelid. Patients with pure aponeurotic dehiscence will have upper lid excursion of at least 10 to 12 mm. Less function than that should alert the surgeon to another possible cause for the ptosis. Patients with congenital ptosis commonly have less than 10 mm of levator function and, in congenital ptosis, precise measurement of the amount of function is critical in determining the amount of levator resection needed or whether to employ frontalis suspension.

Preexisting ptosis from levator dehiscence may be exacerbated if blepharoplasty is performed without surgical repair of the levator. In bilateral cases the surgeon must carefully explain to the patient what the lid position will be following surgery. Asymmetric ptosis is common, in which a more severely ptotic eyelid on one side masks a lesser degree of ptosis in the opposite eyelid. In this situation, an unconscious effort on the patient's part will cause normalization of position in the less ptotic lid, making it appear that only the more ptotic lid needs correction (Herring's law). However, if only the more ptotic lid is corrected, the voluntary effort will cease and the ptosis will then appear on the nonoperated side. It is important to recognize this asymmetry and compensatory effort preoperatively by having the patient alternately cover and uncover the eyes. Occlusion of the more ptotic eye usually allows relaxation of the less ptotic or nonptotic eye, revealing true ptosis. Bilateral ptosis surgery is needed to prevent the asymmetry.

This patient exhibited levator dehiscence on the left following upper lid blepharoplasty. The patient is seen (*right*) after levator repair and preaponeurotic fat advancement.

Differential Diagnosis and Pseudoptosis

Many conditions mimic ptosis but are not true ptosis and should be differentiated from it. Retraction of the opposite lid from *Graves' disease*, in many cases, may simulate ptosis. *Enophthalmos* may simulate true ptosis, because the globe is recessed and the upper lid migrates downward to a lower position. Contralateral exophthalmos may also cause an upward movement of the lid, producing a relative enophthalmos and ptosis on the opposite side.

This patient with Graves' disease had unilateral upper eyelid retraction on the right side, causing pseudoptosis on the left. Lagophthalmos of the right upper eyelid was evident in downgaze (Von Graefe's sign), consistent with Graves' disease.

This patient with ptosis of the right upper lid underwent corrective surgery. A CT scan of the right orbit revealed a mass in the lacrimal gland area consistent with lymphoma.

This young woman had acquired ptosis of the left upper lid. The CT scan shows en plaque meningeoma as the underlying pathologic condition.

Any *mechanical pressure* on the lid, such as heavy skin folds, eyelid edema, or tumor, can produce a downward position of the lid margin and, in many cases, may be difficult to differentiate from a true ptosis. *Guarding* or *squinting* in the presence of an irritative phenomenon may also simulate ptosis.

Spasm may occur with aberrant regeneration of a seventh nerve palsy, hemifacial spasm, or benign essential blepharospasm. Abnormal closure of the eyelid may occur with regeneration of the seventh nerve following palsy or paresis. This is seen as eyelid closure when the patient smiles or contracts his or her lower facial muscles, and it can be misinterpreted as ptosis. In these cases of spasm closure, the lower lid will also elevate as the upper lid comes down.

This patient had a narrowing of the left fissure with lower facial muscle contraction (*left*). The patient exhibits misdirected regeneration of a left seventh nerve palsy. The patient is seen with lower facial muscles relaxed and opening of the eyelid (*right*).

Congenital Versus Involutional Ptosis

In evaluating patients, one must distinguish congenital ptosis from acquired ptosis. Surgical procedures for acquired ptosis and congenital ptosis are entirely different. Although aponeurotic repair is effective for acquired ptosis, it usually has little effect on congenital ptosis, which is the result of a developmental dystrophy in the levator muscle itself—an absence of striated muscle fibers with fibrosis. In congenital cases, the levator muscle is inelastic and stiff and does not respond to aponeurotic repair. Patients with acquired ptosis have a more contractive, elastic muscle. The stiffness of the lid is a diagnostic sign for congenital ptosis and causes lagophthalmos in downgaze. This can be an important diagnostic aid in the absence of history, when one wishes to differentiate congenital ptosis from levator dehiscence. In ptosis from levator aponeurotic dehiscence, stiffness or lagophthalmos in downgaze will not be present. Congenital ptosis only responds surgically to graded levator resection or frontalis suspension.

This young woman has congenital ptosis. When she gazes downward, lagophthalmos is evident, and there is a higher lid position on the ptotic side because of the stiff dystrophic levator muscle.

Evaluation of Preblepharoplasty Patients

- Rule out other causes of ptosis.
- Evaluate both eyes for ptosis by alternately occluding each eye.
- Differentiate congenital from involutional ptosis.
- Inform the patient that ptosis surgery is imprecise.
- Inform the patient that even in the best of hands, a subsequent revision procedure may prove necessary (revision rate 10% to 20%).

Preoperative Planning

An anatomic aponeurotic repair is the senior author's preference for ptosis correction. As mentioned previously, patients undergoing aponeurotic surgery should have, by selection, excellent levator function with only an aponeurotic defect or dehiscence. Other procedures that have been used in lieu of aponeurotic surgery are Putterman's mullerectomy and the Fasanella tarsomullerectomy. Although we do not use the procedure, Putterman's mullerectomy is well accepted as safe and predictable in certain patients. It does require an additional row of stitches on the undersurface of the upper lid, which seems unnecessary if one is performing ptosis surgery combined with an external upper blepharoplasty. The Fasanella-Servat procedure is still used by some ophthalmic surgeons; however, it does involve excision of a portion of the tarsal plate and is nonanatomic in nature. Corneal complications may occur with this pro-

cedure, and any needed reoperations are rendered much more difficult after it has been performed. It has been generally replaced by the more anatomic, aponeurotic repair approach to ptosis surgery for these patients, as described next.

Operative Technique

Anesthesia

Some surgeons favor performing aponeurotic repair with the use of local anesthesia and sedation, having the patient voluntarily open his or her eyelids while the surgeon adjusts until the eyelids have reached the desired levels. This requires that there be no paresis of the levator from a local anesthetic. Local anesthesia is achieved with a supraorbital nerve block for the lid and infiltration of the eyelid crease area with 0.50 to 0.75 ml of short-acting infiltrative anesthetic placed along the site of the intended lid crease, just beneath the skin, with a minimal amount in the nasal lid. In most cases anesthesia is achieved without loss of levator function.

However, this approach can be frustrating: variations in the local anesthetic may cause levator akynesia, an epinephrine effect on Müller's muscle that causes inappropriate lid retraction, and anomalous movement with variations in depth of sedation and patient cooperation. Because of these problems, we have abandoned this method in favor of an anatomic approach with the patient under general anesthesia or full local anesthesia.

Technique

Exposure for aponeurotic surgery

Skin marking and tissue excision are outlined. A lid crease incision is made at the desired level, usually at the upper border of the tarsal plate (approximately 9 to 10 mm above the lash line). The desired amount of skin and muscle above the crease can then be removed. An opening through the orbital septum must be made for surgical exposure. In the aesthetic patient, we think that an “open-sky” approach is necessary, with full exposure of the preaponeurotic space.

The orbital septum must be incised or partially excised, as in the open-sky technique, to expose preaponeurotic fat, the levator aponeurosis, and the musculoaponeurotic junction, which are the landmarks for aponeurotic repair. In some cases, the levator aponeurosis may appear relatively intact at the upper tarsal edge; however, in many cases it is rarefied and stretched, allowing Müller's muscle and the superior arterial arcade to be visible near the superior edge of the tarsus.

The aponeurosis is marked at the superior tarsal border with methylene blue and is incised just inside the superior edge of the tarsal plate to avoid traumatizing the superior arcade. In aponeurotic surgery it is not necessary to disturb Müller's muscle or the superior vascular arcade, thus reducing the amount of bleeding during the procedure.

The anterior view of the upper lid shows dissection of the levator aponeurosis. The cross-section depicts the structures after dissection.

After the levator has been dissected free from Müller's muscle and the musculoaponeurotic junction is exposed by retraction of the preaponeurotic fat, a 6-0 suture, with a small cutting needle, is introduced half-thickness within (2 to 3 mm) the upper edge of the tarsal plate. This suture is the central lifting suture and should be placed in the exact vertical line with the pupil. This aspect is important when dealing with involutional patients who have a lateral displacement of the tarsal plate.

The position of the central lifting suture in the tarsus is demonstrated above. On the left, a more central position in a normal, youthful upper lid is shown. The image on the right shows the position of suture placement that is usually needed in adult levator dehiscence to produce a normal contour. Alignment with the pupil is needed because of a lateral shift of the tarsus.

On the left is an anterior view and on the right a cross-sectional view of suture placement through the musculoaponeurotic junction. A double-armed suture is used, which then can be brought underneath the levator through the junction of the upper edge of the aponeurosis and the levator muscle, the musculoaponeurotic junction. The central suture is the lifting suture for the upper lid, and tightening this suture provides the desired elevation. Nasal and temporal sutures are rarely placed, and if placed, serve only for contour adjustment. Approximation of the superior tarsus to the musculoaponeurotic junction of the levator restores the anatomic integrity of the upper lid, resulting in correction of the ptosis.

Quantitation With the Anatomic Method

In bilateral cases, there are surgical conditions that control the final eyelid level: the anatomic symmetry of the surgical repair, intraoperative eyelid gaping, and intraoperative eyelid springback tension.

Whether bilateral ptosis is symmetrical or asymmetrical, the surgery should be performed with:

- Symmetrical dissection of the aponeurosis
- Symmetrical suture placement on the tarsus
- Symmetrical placement at the musculoaponeurotic junction
- Symmetrical tension on the central lifting suture knot

Despite attempted symmetry of surgical technique, there will be slight differences in the tension of pull on the upper lids. These differences can be further neutralized by loosening and tightening the tension of the central suture until the upper lid elevation produces symmetrical gapping of the eye fissure. This can be verified with caliper measurement, as seen here, which depicts the intraoperative measurement of gapping needed to refine the accuracy of upper lid placement.

Springback Test

Even further refinement to the upper lid may be needed. It is well known to ophthalmic surgeons correcting strabismus that despite symmetrical positioning of the eye, subtle differences in tension can affect eye alignment. The same is true in ptosis surgery, so the final adjustment on suture tension is to equalize the “springback” between the two lids. Both upper lids are closed by forced traction with forceps and then released to observe the velocity with which the lid “springs open” to the gapped position. Tension on the central suture is then adjusted until the springback is symmetrical.

True Unilateral Ptosis

The springback test and intraoperative assessment of gapping are not appropriate in cases of unilateral ptosis; only the anatomic landmarks observed at surgery are pertinent. There is a greater incidence of postoperative adjustment in such patients. In many ptosis patients, regardless of the method of quantitation used, some form of postoperative adjustment will be needed. The easiest postoperative adjustment to make is loosening of an overcorrected lid. Most cases of mild overcorrection can be improved by early postoperative stretching. More-persistent overcorrections can be improved a few weeks after surgery by a simple central lid crease incision and clipping of the central suture and adhesions, followed by massage. Undercorrections require reoperation.

This patient with Graves' disease is seen after levator surgery; she exhibits early signs of overcorrection. To address the overcorrection, a program of stretching exercises was initiated for 10 days. These exercises produced an improvement, as can be seen in the final eyelid position. No surgical revision was required.

This patient with bilateral ptosis underwent blepharoplasty and ptosis repair. She is shown preoperatively and 10 days after surgery with overcorrection of the left upper lid. To address this problem, stretching exercises were initiated. Six weeks after surgery, the patient's lid had responded to the stretching exercises, and no surgical loosening was required.

Because of the inherent imprecision of any ptosis surgery, postoperative surgical revisions are necessary in 10% to 20% of cases. In a series of patients operated by the author (C.D.M.) using an anatomic approach, general anesthesia, and in conjunction with other aesthetic surgical procedures, the revision rate was lower (approaching 2%), and the surgery was much less tedious for the surgeon and the patient. The following three cases demonstrate the results of a series of patients who underwent aponeurotic repair in conjunction with aesthetic surgery.

Results

This patient is shown before and after upper blepharoplasty and lower lid midface surgery, combined with tarsal levator repair. No postoperative adjustments were necessary.

Upper blepharoplasty and lower lid midface surgery was used to treat this patient's problem. She also underwent tarsal levator repair, an endoscopic brow lift, and a lower face lift. No postoperative adjustments were necessary.

In this patient, levator repair was done to the right upper lid, combined with a lower lid midface lift, an endoscopic brow lift, and a lower face lift. The patient required secondary surgical loosening of the right upper lid, which was performed as a minor outpatient procedure. With a small amount of local anesthetic placed in the central lid crease, a small incision was made to release some of the aponeurotic attachments. Postoperative stretching exercises were instituted.

Special Problems

Floppy Upper Lid in Males

Floppy upper lids more commonly occur in obese men. Severe distensibility of the upper lid and lower lid requires a reconstructive type of canthoplasty on both upper and lower lids. Failure to resect any redundant upper lid will result in overlapping of the upper lid and poor closure. Subtle variations of this may occur. A canthoplasty type procedure must be performed on the upper lids to stabilize them.

This obese young man exhibits ptosis with floppy lid syndrome in his primary gaze. Distention shows dramatic loss of elasticity in the upper lid. An upper lid canthoplasty is needed to stabilize the lid.

Blepharochalasis Syndrome

Blepharochalasis syndrome is a rare condition that occurs in young people, usually females, characterized by recurrent idiopathic edema of the eyelids. This results in stretching of the skin, levator aponeurosis, and the lateral canthal tendon, and occasionally in atrophy of the nasal fat pad. The patient's ptosis is surgically correctable with aponeurotic repair, but staged procedures are usually required, including lateral canthoplasty, blepharoplasty with aponeurotic repair and dermal fat grafting to atrophied areas.

Tissue changes resulting from the blepharochalasis syndrome are evident in this woman. She had repeated bouts of inflammatory edema during childhood resulting in loss of elastic tissue dehiscence of the levator, loss of the nasal fat pad, lateral canthal dehiscence, and crêpey skin changes. The patient was referred because of “skin growing between her upper and lower lid.” She also has levator dehiscence in addition to canthal dehiscence.

Chronic Progressive External Ophthalmoplegia

Chronic progressive external ophthalmoplegia (CPEO) results from a progressive muscular dystrophy that principally affects the extraocular muscles including the levator muscle. Its onset can be subtle, and it may begin in childhood or adolescence, with gradual development of ptosis. Very early cases may be difficult to recognize because of the absence of diplopia. These patients will develop progressive impairment of ocular rotations and eye protection, and postoperative corneal exposure may be a problem.

This woman has an advanced stage of CPEO. She is shown attempting eye rotation. She has extremely poor levator function and very poor ocular motility and is at severe risk for corneal exposure with any ptosis surgery.

Concluding Thoughts

Patients who request aesthetic eyelid rejuvenation may have associated ptosis, and recognition of the ptosis at the initial consultation is essential. The cause must be established and the ptosis corrected at the time of aesthetic blepharoplasty.

Clinical Caveats

Recently acquired ptosis, in many cases, warrants neurologic evaluation.

Congenital ptosis will not respond favorably to aponeurotic repair.

Adequate eye protective mechanisms are more critical for patients undergoing ptosis surgery than for patients undergoing blepharoplasty.

Acquired ptosis can be a sign of an underlying pathology of the lid or orbit.

Lateral displacement of the upper tarsal plate must be surgically compensated to achieve good postoperative contour.

The vector of pull should be centered over the pupil.

In bilateral cases, symmetry of surgery with fine tuning of suture tension is the most important requirement for postoperative symmetry.

In most patients, one suture is usually enough. Extra suturing will reshape the lid.

Annotated Bibliography

Dortzbach RK, Kronish JW. Early revision in the office for adults after unsatisfactory blepharoptosis correction. *Am J Ophthalmol* 115:68-75, 1993.

The most common complications of levator palpebrae superioris muscle blepharoptosis repair are undercorrection, overcorrection, and abnormalities of the eyelid contour. Previously described nonsurgical as well as surgical methods delay the repair of such complications and introduce the same confounding factors that can affect judgment of the eyelid level as during the initial surgical procedure. The authors present their technique and results in 22 patients who underwent a highly predictable surgical technique to revise unsatisfactory postoperative eyelid positions.

Fagien S. The role of the orbicularis oculi muscle and the eyelid crease in optimizing results in aesthetic upper blepharoplasty: a new look at the surgical treatment of mild upper eyelid fissure and fold asymmetries. *Plast Reconstr Surg* 125:653-666, 2010.

The author presents a simple yet comprehensive approach to upper blepharoplasty that considers both the youthful or desired appearance and the management of upper eyelid asymmetries by preservation or selective treatment of the orbicularis oculi muscle and placement of the upper eyelid crease to improve aesthetic outcomes.

McCord CD. The evaluation and management of the patient with ptosis. *Clin Plast Surg* 15:169-184, 1988.

The author discusses the fundamentals for evaluating and correcting ptosis for a variety of patients. He emphasizes there are many subgroups of ptosis patients that require the ptosis surgeon to have a flexible approach and a repertoire of surgical procedures. In a certain percentage of patients, results will remain unpredictable, and the surgeon must always be prepared to perform revisional surgery. He also stresses that formulas are only a starting point for each surgeon to develop individual variations to obtain the best and most predictable ptosis correction.

Shore JW, Bergin DJ, Garrett SW. Results of blepharoptosis surgery with early postoperative adjustment. *Ophthalmology* 97:1502-1511, 1990.

The authors review 157 cases (207 eyes) of blepharoptosis corrected by external levator resection and present the results. They found early or late reoperation is effective in correcting unsatisfactory results after external levator resection. However, the benefits of early surgery include a reduction in time to final result, the ease with which it is performed, potential cost savings, and the opportunity of correcting unsatisfactory results.

CHAPTER 34

Avoidance and Treatment of Complications of Aesthetic Eyelid Surgery

CLINTON D. MCCORD, JR., FOAD NAHAI

Awareness of the complications that may occur after aesthetic eyelid surgery can help a surgeon to avoid them. In many cases, postoperative complications are visible and obvious; however, on occasion, a patient's result may look acceptable from an aesthetic standpoint but eyelid dysfunction may still be present from subtle changes in eyelid flexibility, position, or movement. For example, even mild lower lid retraction, if accompanied by reduced upper lid closure from excessive skin removal, can produce severe exposure problems, particularly if there are coexisting conditions such as eye dryness or poor eye movement.

Most patients with no history of suspicious eye symptoms preoperatively, or those with a history of a "normal" eye examination in the recent past, are generally good candidates for eyelid surgery. It is safe to assume that contact lens wearers, because of the adequate moisture that is required by the lenses for wear, will be tolerant of the usual stiffness that occurs after blepharoplasty, but there may be exceptions. Patients who have suspicious symptomatology or unusual findings on an eye examination and those with a history of eye problems should be evaluated by slit-lamp examination, tear tests, or consultation with an ophthalmologist.

Complications following blepharoplasty may be as minimal as an unfavorable scar, as devastating as visual loss, or anything in between. The majority of complications in between are mostly related to lid retraction and its consequences. We divide these complications into two categories:

1. The unfavorable aesthetic result in which the basic protective mechanisms of the eyelid are unimpaired, but the patient is realistically displeased by surgical changes, or disappointed with the result, which may not have met expectations
2. Functional complications in which the patient suffers from eyelid malposition or is left with faulty eyelid mechanics so that the eyelid fails to protect the eye

These two categories are not mutually exclusive, and both may have to be addressed.

Early complications following blepharoplasty include bleeding/hematoma and chemosis. Fortunately hematomas following blepharoplasty are rather rare, in our experience less than 1%; on the other hand, chemosis is by far the most common early complication, ranging up to 11.5% in some series. Lid retraction and its consequences represent the majority of late complications and account for most secondary or corrective procedures.

Complications Following Blepharoplasty

Unfavorable Aesthetic Results

Unacceptable scar
Residual skin excess
Overresection or underresection of fat
Overresection or underresection of orbicularis oculi muscle
Changes in eye shape
Eyelid asymmetry

Functional Problems

Chemosis
Hematoma
Exposure problems
Infection
Lid retraction
Ptosis of the upper eyelid
Muscle palsy (most commonly the inferior oblique muscle)
Loss of vision

Early Complications

Hematoma

Eyelid Hematoma

Predisposing factors for hematoma following blepharoplasty are the same as those following a face lift, including hypertension, increased venous pressure, nausea, vomiting, and anxiety. (See Chapter 50 for a detailed discussion.)

A hematoma confined to the preseptal area is not usually a threat to vision; however, it may affect the surgical result. With a skin-muscle flap, hematoma may result in scarring and skin and lid retraction as it resolves. Therefore it is advisable to aggressively evacuate or drain any blood collection after blepharoplasty.

Orbital Hematoma

Postseptal bleeding causing an intraorbital hematoma is a serious matter. Profuse intraorbital bleeding may increase orbital pressure, thereby compromising optic nerve function. If the hematoma is mild, not expanding, and produces no detectable visual or pupillary changes, it can be treated conservatively by observation, systemic steroids, and cold compresses. Severe bleeding producing intense orbit and pupillary or visual changes is an emergency requiring urgent intervention. Immediate lateral canthal lysis, removal of sutures, and evacuation of hematoma is performed at the patient's bedside. Time should not be wasted in trying to return the patient to the operating room. Once the pressure has been relieved, a search is made for the source of bleeding, which is then cauterized.

An orbital hematoma is most likely to occur during the immediate postoperative period. Therefore it is important that the patient be observed by a trained, responsible person in the recovery area. Any significant change in orbital volume or severe pain following blepharoplasty should alert the nurse and the surgeon to the possibility of an orbital hematoma. Severe eye pain in the recovery room may also signal corneal abrasion or another ocular event. It is our practice to avoid pressure bandages on the eye and to apply ice compresses intermittently.

Types of Hematomas and Recommended Treatment

Eyelid Hematomas

Skin-muscle flap

Observation

Skin flap

Drainage (Bard-Parker No. 11 blade or removal of stitches)

Orbital Hematomas: Mild, Without Pupillary Changes

Observation/drainage

Systemic steroids

Cold compresses

Orbital Hematomas: Severe, With Pupillary and/or Visual Changes

Remove stitches and evacuate hematoma

Large canthotomy and cantholysis

Orbital decompression if edema becomes chronic

Chemosis

Postoperatively, the conjunctiva on the surface of the eye may swell, retain fluid, and become chemotic. If this occurs, a corresponding dry spot (*dellen*) forms on the cornea. The initial cause of this swelling is likely multifactorial and may be the result of lymphatic drainage obstruction, poor eye closure with exposure, and an inflammatory reaction. This problem is much more likely to occur in patients who have preexisting conjunctivochalasis (redundant conjunctiva), significant swelling, and fluid retention postoperatively, or who do not use lubricants postoperatively. On occasion, the surgeon may see this condition develop intraoperatively. In such a case, the bulbar conjunctiva can be snipped in the inferior fornix without consequences. If significant excision is performed, a 6-0 plain gut suture can be inserted in the bulbar conjunctiva near the fornix.

Postoperatively, if mild chemosis is diagnosed early, 2 drops of 2.5% phenylephrine (Neo-Synephrine) and 2 drops of dexamethasone eyedrops can be placed in the chemotic eye, which alleviates the problem in many cases. These drops are commonly used by ophthalmologists who perform strabismus surgery, because they suppress inflammation and stabilize the vessels of the conjunctiva. The patient should be monitored during treatment with these eyedrops. The use of steroid drops in a patient with glaucoma or a family history of glaucoma may lead to worsening of the condition. Treatment is usually limited to 5 to 7 days. If chemosis persists or becomes more severe, the eyelids are bandaged closed for 24 hours or more. The proper technique to immobilize eyelids with bandaging (eyelids must stay closed) is as follows:

Three oval eye pads are used.

The bottom pad is folded, moistened with saline solution, and placed against closed eyelids.

Two dry pads are placed on top and firmly taped in place with multiple strips of tape.

The tape is anchored on the central forehead, tightened over the eye pads, and extended obliquely down to the cheek.

The patient should not be able to open his or her eye under the pads.

If chemosis recurs after patching, and if the eye has little inflammation, topical phenylephrine (Neo-Synephrine) drops and topical anesthetic drops are instilled, and the billowing area is incised and resected with sharp scissors. The incision in the conjunctiva must go through the tenon capsule to allow fluid to escape. Once this procedure is completed, the patch is reapplied.

Late Complications

Most if not all late complications are related to lid retraction, its consequences, and alterations in eyelid closure mechanics. A brief review of eyelid mechanics and innervation follows to identify the anatomic causes of these problems.

Eyelid Mechanics and Innervation

Eyelids have multipart mechanics contributing to orbicularis muscle function. Contracture occurs in different parts of the muscle, depending on the function needed. There is interplay between orbicularis contracture and counter pull at the eyelid attachment at the lateral canthus. This interplay affects eyelid blinking and eye fissure shape.

Eyelid Movement: Division of Labor in the Orbicularis

In previous studies involving segmental surgical removal of the orbicularis oculi muscle in large series of patients with blepharospasm, it was shown that only the orbicularis muscle in the inner canthus is responsible for everyday eyelid tone, movements associated with blinking, and normal eyelid closure. This section of the orbicularis also provides the “motor” for the lacrimal pump mechanism for the drainage of tears. The rest of the orbicularis, the extracanthal orbicularis, is responsible only for emergency and emotional eyelid closure, such as squeezing, squinting, and animations of expression.

Anatomic classification of the orbicularis into the orbital, preseptal, and pretarsal orbicularis is convenient for surgical labeling, but a functional classification of the orbicularis into an inner canthal orbicularis and an extracanthal orbicularis should be adopted for better understanding of eyelid function.

These illustrations show the division of function (division of labor) seen in the orbicularis muscle. The extracanthal orbicularis is primarily responsible only for accessory squeezing movements and expression of the eyelid. The inner canthal orbicularis, as shown in the upper illustration (*purple-shaded area*), is responsible for normal blinking movements, eyelid tone, and the lacrimal pump mechanism. The larger areas shown at the lower left demonstrate the vector of pull of the intercanthal orbicularis toward the nose and the counterpull on the eyelids by fixation of the lateral canthal tendon.

Eyelid Innervation: Division of Innervation of the Orbicularis

It follows that because there is a division of labor in orbicularis muscle function, there is also a duality of innervation of the orbicularis. Electromyographic (EMG) studies, clinical observations, and anatomic studies have shown this to be the case. The extracanthal orbicularis is supplied by the zygomatic branch of the facial nerve, whereas the inner canthal orbicularis is supplied by a vertical extension of the buccal branch of the facial nerve.

The dual innervation of the orbicularis muscles is illustrated. Branches of the zygomatic portion of the facial nerve supply the extracanthal orbicularis, and vertical branches of the buccal branch of the facial nerve supply the canthal orbicularis and corrugator muscles.

Loss of innervation from the zygomatic branch of the facial nerve to the extracanthal orbicularis can occur, but in the absence of lower lid laxity it will produce little change in eyelid position or tone as long as the buccal branch innervation to the inner canthus remains intact. Standard surgical incisions in the pretarsal or preseptal orbicularis external to the inner canthus cause no abnormalities in lower eyelid position or tone. With regard to the effect of subciliary incisions, recent EMG studies show that microdenervation of the pretarsal orbicularis muscle does not occur, even if the recording electrode is placed directly into the surgical incision line. However, loss of eyelid innervation from the buccal branch of the facial nerve to the inner canthal area will cause profound changes in eyelid function, with reduction or absence of eyelid blinking, poor lower lid tone and position, and a weakening of the lacrimal pump mechanism, causing tearing.

Lateral Canthal Anchoring

The mechanics of eyelid closure, the normal blinking movements of the upper and lower lid, require firm attachment at the insertion of the lateral tendon for counterpull. Because contracture of the orbicularis in the inner canthus is responsible for blinking of the eyelids, if it is unopposed, an abnormal nasally directed eyelid movement occurs with each blink. Firm anchoring laterally is needed for counterpull against canthal contracture to convert the vector of the blink movement into a vertical one for proper eyelid closure. Patients who lack lateral canthal anchoring suffer from faulty eye-blinking mechanics. The nasal movement of the eyelids that occurs with each blink results in “fish-mouthing” of the eyelids when the individual attempts eyelid closure. This situation can cause lagophthalmos and eye exposure of varying degrees.

The structures in the eyelids that are responsible for blinking movements are shown. The inner canthal orbicularis, with its contracture, provides the motor for the eyelid blink but can only be effective if there is firm counterpull of the eyelids laterally at the outer canthus. The top illustration shows normal closure with firm lateral canthal anchoring. The bottom illustration shows reduced closure, to the point of fish-mouthing, with weak or dehiscent lateral canthal attachments.

AESTHETIC GOALS IN THE LOWER LID: A MIDFACE AESTHETIC UNIT

Normally the inferior arc of the orbicularis oculi muscle and the underlying suborbicularis oculi fat (SOOF) span the eyelid and orbital rim area in the midface. With aging there is sagging or ptosis of the orbicularis muscle, accompanied by loosening of the orbitomalar ligament, which causes a downward descent of the SOOF and malar fat. This facial descent results in a loss of padding over the inferior orbital rim and a loss of cheek fullness, characteristics that are inconsistent with a youthful appearance. This descent is usually accompanied by herniation of fat as well as skin laxity in the eyelid.

The skeletonization of the orbital rim area associated with age is a major contributor to the aging appearance in the midface area. Surgery that fails to address the eyelid and cheek area as an aesthetic unit falls short of producing a true reversal of aging changes in this area. Techniques that use supraplacement of the inferior arc of the orbicularis muscle to reposition the midcheek upward correct the underlying problem of ptosis of the orbicularis. In patients undergoing primary cosmetic surgery, as the skin of the lower lid and midface is recruited upward, the resulting skin redundancy can be excised. In patients undergoing reoperation with lower lid retraction caused by excessive skin removal, the additional skin recruited by upward movement of the orbicularis introduces needed skin into the lower lid. In corrective surgery, the technique of orbicularis redraping is a valuable tool that allows the surgeon to avoid skin grafts in patients with a shortage of skin in the lower lid.

Eye Fissure Shape

In patients undergoing aesthetic eyelid surgery, a youthful configuration of the eyelid fissure is needed to reduce the perception of aging in the eyelids. The elements that define eye fissure shape are the position of the eyelid margins and the shape of the exposed scleral triangles on either side of the cornea. The size of the cornea is uniform in all persons, but the shape of the scleral triangles may vary. Generally, the nasal scleral triangle is smaller, and the lateral scleral triangle is larger and more pointed. In most individuals, the position of the lateral canthus is slightly higher than the inner canthus and is at the level of the inferior edge of the pupil.

The youthful eye fissure shape shown above is defined by the position of the eyelids and the exposed sclera on either side of the iris, the nasal (medial) scleral triangle, and the lateral scleral triangle. The standard position of the lateral canthus is in line with the inferior edge of the pupil and is slightly higher than the inner canthus. Eye fissure changes that occur with age are shown in the eyes at right. In a deep-set eye, the eye fissure becomes smaller, with a reduction in the size of the lateral scleral triangle. In a prominent eye, downward bowing of the lower lid is evident.

The shape of the scleral triangles and eye fissures is seen in the eyes of these young women. With aging there is relaxation of lateral canthal attachments, which may cause the eye fissure to change in shape according to eye prominence. In persons with normal or deep-set eyes, the fissure tends to become rounder and smaller. In persons with prominent eyes, a downsliding of the lower lid, scleral show, and enlargement of the lateral scleral triangle may occur. Proper canthal anchoring restores a more youthful look to the eye fissure by changing the shape of the fissure and the shape of the lateral scleral triangle.

This woman is shown before and after lateral canthopexy and a midface lift. The eye fissure has been corrected from rounded and small with age (*left*) to a more open, elliptical, youthful shape (*right*).

A change in eye fissure shape is demonstrated in this man. After canthal anchoring, the shape of his eye fissure changed from rounded (*left*) to a more youthful, elliptical shape (*right*).

It has been shown mathematically that protrusion of the eye against the eyelid affects the shape of the eye fissure. Upper lid curvature is determined almost exclusively by indentation of the globe on the eyelid. Lower lid curvature is determined by a combination of globe indentation and the position and tone of the lateral canthal tendons. Lateral canthal anchoring has a powerful influence on lower lid position and curvature.

Techniques of Lateral Canthal Anchoring

Strengthening the eyelid attachments at the lateral canthus can take the form of a pexy procedure, with plication of the canthal tendons or canthoplasty, cantholysis, and shortening of the lower lid with reattachment to the lateral periosteum. In patients with lower lid laxity, reinforcement with shortening of the lower lid is necessary.

The two common methods of lateral canthal anchoring are illustrated. With canthopexy, a mattresslike suture attaches both the upper and lower tendons to the periosteum inside the orbital rim. With canthoplasty, the lower lid is shortened to compensate for laxity. In both cases the upper lid is included in the anchoring to the orbital periosteum. Whichever procedure is used, the axial vector of lid anchoring must travel inside the lateral orbital rim so that the lower lid will be flush with the curvature of the globe.

The normal vectors of attachment of the lateral canthal tendons and the orbicularis muscle are shown. The lateral canthal extension of the tarsoligamentous sling inserts well inside the orbital rim, whereas the orbicularis muscle inserts externally on the orbital rim.

Indications for Canthoplasty Versus Canthopexy

Significant laxity of the tarsoligamentous sling must be addressed surgically by tightening or shortening the lower lid to stabilize it and prevent postoperative ectropion or buckling when a blepharoplasty is performed.

This patient, who had lower lid laxity after blepharoplasty, demonstrates outward buckling of the lower lid with ectropion. No shortening of the tarsoligamentous sling was performed. There is a disparity in tone between the anterior lamella (orbicularis) and the posterior lamella (tarsoligamentous sling), which causes the lid to buckle outward.

The *intraoperative distraction test* is the best method for detecting lower lid laxity. Preoperative eyelid distraction tests have been described in the past, but we think it is more meaningful to apply the distraction test intraoperatively. No more than 1 to 2 mm of distention from the globe should be seen with outward traction on the lower lid with the patient in the recumbent position intraoperatively. In addition, there should be a firm “snap back” to the globe after distention. If this amount of tension is not seen in the lower lid, a tightening procedure of the tarsoligamentous sling of the lower lid must be performed.

In patients with laxity of the tarsoligamentous sling, tightening only the orbicularis muscle will not correct internal lower lid laxity and can produce outward buckling of the lid because of redundancy in the posterior lamella. Tightening of the tarsoligamentous sling itself must be performed.

Either canthopexy or canthoplasty is used until the proper tension is obtained. If canthopexy is tried first and the tension of the lower lid against the globe does not seem adequate, or there seems to be redundant tissue at the lateral canthus, the lower lid should be resected and canthoplasty performed.

Variations in Placement of Lateral Canthal Anchoring

As mentioned earlier, the pull of lateral canthal anchoring on the eyelids against the globe will influence the shape of the eyelid fissure according to the prominence of the eye. To produce the desired youthful fissure shape, variations in placement of the anchoring are used according to eye prominence. Because the lateral pull of canthal anchoring of the lower lid results in changes in the size, shape, and position of the lateral scleral triangle, different placements of anchoring must be used in patients with differences in eye prominence.

The position of the lower lid changes in response to traction at the lateral canthus. The lower lid position will either remain stationary, "clothesline" downward, or clothesline upward in response to the lateral pull of canthal anchoring, with differences in eye prominence. Lower eyelid movement depends on whether the eye is deep-set (less than 15 mm), standard position (15 to 18 mm), or prominent (more than 18 mm). In an eye with standard prominence, a lateral pull in line with the inferior edge of the pupil will maintain a good lower lid position. In a deep-set eye, this same vector of pull will result in upward clotheslining, giving the patient a small

eye fissure postoperatively. In a prominent eye, the same pull will cause downward clotheslining.

During a lower lid blepharoplasty, if the surgeon fails to take these factors into account and fails to modify lateral canthal anchoring accordingly, abnormalities of the eye fissure may result. Preoperatively, the proper placement of canthal anchoring can be planned according to preoperative measurement of eye prominence as measured with an exophthalmometer.

This approach to treatment is offered as a general guideline; the surgeon makes the final determination on anchoring after assessing the behavior of the lower lid intraoperatively. During surgery, if the final resting position of the edge of the lower lid is at the desired level in relation to the cornea (usually just inside the lower limbus), the position of anchoring can be deemed adequate.

The proper vectors of canthal anchoring are demonstrated in patients with deep-set eyes, eyes with standard position, and prominent eyes. In patients with deep-set eyes, canthal anchoring should be directed more downward and internally to compensate for globe curvature. For patients with standard eye prominence, canthal anchoring should be placed at the level of the inferior edge of the pupil inside the orbital rim. For patients with prominent eyes, the vector of anchoring should be more upward, with mild supraplacement.

Standard Eye Prominence

Lateral anchoring for an eye with standard prominence (16 to 18 mm) is usually best accomplished by placement at the level of the inferior edge of the pupil.

The image on the right depicts positioning of canthal anchoring in the various situations of eye prominence. The highest placement is for a prominent eye. The lowest placement is for a deep-set eye. In the left image, the proper vector of fixation is indicated by the black arrow. The red arrow indicates a placement that is too anterior in most cases.

The Deep-Set Eye

In a patient with deep-set or inwardly recessed eyes, a lower lid clotheslining upward may occur that narrows the fissure and reduces the size of the lateral scleral triangle. This may cause the patient to complain of “little, squinty eyes” postoperatively. In these patients with deep-set eyes (less than 15 mm), anchoring is placed more inferiorly and more internally to prevent the upward clotheslining of the lower lid that may occur (see the preceding two figures). This also prevents narrowing of the lateral scleral triangle and postoperative patient complaints of “small eyes.”

This patient with deep-set eyes (15 mm) is shown before a cheek lift (*left*). Because she was at risk for narrowing of the eye fissure with standard placement of canthal anchoring, a modified approach was used. On the right, the patient is shown after a midface lift and canthal anchoring, which was modified with downward and inward placement to compensate for her enophthalmos.

The Prominent Eye

In a patient with prominent eyes, tightening the lower lid in the standard vector can cause a clotheslining effect that produces a bowing downward of the lower lid or, in more severe cases, scleral show. Currently we depend on slight supraplacement of lateral canthal anchoring to position the lower lid upward to counteract this effect in milder cases. We have found that the position of the canthal anchoring in the prominent eye should not be higher than the center of the pupil, particularly in patients with more severe eye prominence.

This illustration depicts the limitations of supraplacement of the lateral canthal tendon, which can result in the weakening of upper lid closure because of the mechanical factors involved. Canthal anchoring should not be supraplaced above the mid-level of the pupil; leverage of upper lid closure is lost as the canthus is supraplaced. This is particularly true in patients with prominent eyes.

Limitations of Canthal Supraplacement

If certain limits of lateral canthal supraplacement are exceeded in patients with increasingly prominent eyes, there is an adverse effect on upper lid closure. This is because the fulcrum of upper eyelid movement may slide upward past the vertex of the cornea as lateral anchoring moves upward, which causes reduced closure of the upper lid with lagophthalmos. Increased tightening of the upper lid can aggravate this situation; it is analogous to the clotheslining effect that occurs with tightening of the lower lid in these patients. Excessive manipulation of the lateral tendons upward may also intrinsically weaken the upper tendon attachment.

Preoperative

Postoperatively

This patient with prominent eyes and preexisting scleral show is shown preoperatively and postoperatively. Postoperatively, excess supraplacement of the canthal angles is evident because of the retinacular suspension used to elevate the lower lid margin. Note the weakening of upper lid closure.

Other Compensatory Procedures in Patients With Prominent Eyes

If mild lateral canthal supraplacement does not elevate the lower lid enough, the first surgical step to be used to counteract any clotheslining tendency is a *release or recession of the inferior retractors*, capsulopalpebral fascia (CPF), in the lower lids. A gain of 1 to 2 mm in the lower lid position against scleral show can be achieved with CPF recession.

This illustration shows recession of the inferior retractors (CPF) of the lower lid to elevate the lid margin.

This woman with prominent eyes (greater than 18 mm) is shown before and immediately after canthal anchoring with slight supraplacement combined with recession of the CPF in the lower lid. There is normalization of the lateral scleral triangles.

In patients with more severe eye prominence, loosening the CPF may not provide enough lid elevation to prevent postoperative scleral show, and *spacer material must be inserted* in the posterior lamella of the lower lid. For spacer placement, we prefer a full-thickness blepharotomy in the posterior lamella 6 mm below the lower lid margin (sparing the inferior arcade, which is approximately 4 mm below the lid margin). Most of the blood flow to the lower lid comes from the nasal arterial complex, so care is taken not to dissect or cauterize unnecessarily in this area. It is convenient to use AlloDerm of sufficient thickness as a spacer material in previously unoperated patients.

Incision of the inferior retractors (CPF) and conjunctiva is shown, with full-thickness blepharotomy of the posterior lamella of the lower lid and insertion of spacer material to elevate the lid margin.

This patient with prominent eyes (greater than 19 mm) is shown before and after midfacial lid surgery combined with upper lid brow surgery, in which a primary spacer of AlloDerm was used to prevent downward clotheslining and scleral show.

Our present approach for preventing postoperative problems in patients who have prominent eyes is a progression from conservative lateral canthal supraplacement to recession of the inferior retractors, followed by insertion of a spacer to produce a desirable eye fissure shape.

Lower Lid Complications and Their Treatment

Abnormalities of eye fissure shape and lower lid retraction or ectropion are the most common problems that may be seen after aesthetic lower lid surgery. Shape deformities range from a simply undesirable eye shape (such as rounding, bowing, or narrowing of the lateral scleral triangle) to lid malposition. Commonly these problems result from inappropriate canthal anchoring. Patients with poor anchoring may also have poor eyelid closure mechanics. The causes of ectropion or downward retraction of the lower lid are as follows:

- Overzealous skin removal
- Failure to surgically anchor supporting elements of the eyelid (the lateral canthal tendons or the orbicularis muscle flap)
- Failure to recognize preexisting lower lid laxity
- Failure to recognize significant variation in eye prominence

Lower lid malposition may have medical consequences in addition to aesthetic ones. Postoperative exposure can be particularly intensified if lagophthalmos in the upper lid is present as well.

Nonsurgical Management

In the early postoperative period, some edema, with its fluid accumulation, causes thickening, which exacerbates lower lid malposition. The conservative approach is essential in patients who still have edema and thickening of the lower lid. It may take several weeks for the fluid to be resorbed, the edema to resolve, and the lid tissue to soften and elevate. Upward massage is therapeutic.

Watchful waiting and reassurance constitute the best approach during the early recovery. If mild edema is accompanied by excessive stiffness in the eyelid skin or subcutaneous tissues, judicious injection of steroids may be useful. Caution must always be exercised when injecting steroids to avoid subcutaneous fat atrophy, thinning of the skin, and telangiectasia.

Corrective Surgical Procedures

Lower lid retraction or malposition that does not resolve with conservative measures requires surgical correction. These corrective procedures may have to be staged, depending on the severity of the problem and the desire to avoid external skin grafts in certain patients.

We classify lower lid complications in the following three broad categories:

1. Lower lid retraction
2. Eye fissure shape changes
3. Eyelid closure mechanics

These problems may occur independently, but for many patients they appear in combination.

Common procedures to correct lower lid complications are anchoring (or reanchoring) of the lateral canthus and anchoring (or reanchoring) of the inferior arc of the orbicularis muscle. Both structures offer support for repositioning the lower lid, and each, if appropriately anchored, can restore an undesirable eye fissure shape.

This is an example of a patient with eye fissure narrowing after blepharoplasty. The patient complained of “little bitty eyes” after blepharoplasty; note the narrowing of her eye fissures. After canthal reanchoring modified with downward and inward placement, she was pleased with the enlargement of her eye fissures and thought that her eyes had a more normal shape.

On the left is a close-up of a patient with deep-set eyes after a lower lid blepharoplasty in which the proper type of canthal anchoring was not performed. She had a marked reduction in the size of the lateral scleral triangles in both eyes. On the right, after canthal anchoring with downward, inward placement to compensate for the deep-set eye, enlargement of the lateral scleral triangle is shown (*see red outlines*). If skin shortage is a significant factor in lower lid retraction, canthal vertical anchoring of the inferior arc of the orbicularis muscle will recruit skin upward into the lower lid and will, in most cases, correct retraction without the use of a skin graft. Insertion of spacer material into the posterior lamella of the lower lid is particularly useful in patients with prominent eyes and those with retraction caused by scarring of the middle lamella. Spacer material, interposed after scar release, acts as a barrier against postoperative scar contraction. Autologous material such as dermis, ear cartilage, or hard palate is best used in reoperative cases.

Canthal Anchoring (Reanchoring)

In patients who have minimal scarring and an intact lateral rim periosteum, canthal reanchoring may be performed as one would in an unoperated patient. In patients with unusual scarring or tissue deficiency in the canthal area, extra tissue may be needed for lateral reinforcement. In milder cases, a periorbital rim–based periosteal strip can be used for support.

Techniques of canthal anchoring using reinforcement with additional tissue are shown. A reflected flap of lateral rim periosteum can be used as a reconstructive procedure at the lateral canthus and can act as additional support. In lieu of periosteum, free grafts of fascial tissue, either temporalis or fascia lata, can be used for additional support of canthal reanchoring.

A free fascia patch graft may also be used. This approach, in which additional soft tissue is introduced, is particularly helpful in cases in which there is a shortage of eyelid tissue in the lateral lid.

After an earlier eyelid surgery, this patient had a loss of normal lateral canthal attachments in the right eye and phimosis from tissue loss in the left eye. Both lateral canthi were reconstructed with reanchoring and periosteal flap placement, as shown on the right.

Our procedure of choice for the most secure canthal anchoring is refixation of the lateral canthus through a drill hole in the lateral orbital rim. This is a useful technique in patients with poor periosteum and weakness of soft tissue support at the lateral canthus. It is best used for patients with severe distortion of the eye fissure or patients who have poor eyelid closure caused by lateral anchoring deficiency. Drill-hole fixation enhances the permanency of anchoring.

The technique of canthal anchoring using drill-hole fixation to the lateral orbital rim is shown. A single drill hole can be used. The double-armed suture (4-0 Mersilene) is passed through the single drill hole and secures the canthus inside the lateral orbital rim. The double-armed suture can then be fixed to the deep temporal fascia. The use of a single drill hole allows greater precision in canthal placement and possibly a more secure attachment to the orbital bone.

The doubled-armed suture attached to the canthal structures is brought out through the drill hole and secured to the deep temporal fascia.

On the left, this patient shows deformity of the right canthus that had resisted conventional forms of canthal reanchoring; on the right, the same patient is seen after drill-hole canthal anchoring.

The need for drill-hole canthal fixation commonly occurs in patients with prominent eyes who also have eyelid retraction and stiffness of the upper and lower lids. In these patients a double drill-hole fixation is necessary in which the lateral tendons of the upper and lower lid are independently fixed to drill holes in different positions.

To obtain the proper vectors of pull at the lateral canthus to ensure good lid closure, a crisscross attachment can be used. This is particularly important in patients with prominent eyes and poor closure. The vector of pull that improves closure in the upper lid is obtained by placing it in the inferiorly placed drill hole. A cantholysis is performed, and the edge of the upper lid is attached to the lower drill hole. The lateral tendon of the lower lid can be placed in the superiorly placed drill hole, allowing a higher supraplacement of the lower lid without affecting upper lid closure. This improves the upper lid closure mechanics and also allows more supraplacement of the lower lid. This crisscross drill-hole fixation is commonly used in conjunction with the other reconstructive procedures.

Vertical Reanchoring of the Inferior Orbicularis Muscle

The upward redraping of the inferior arc of the orbicularis, with tightening and firm attachment to the temporal fascia, will add support to the lower lid.

The skin is recruited upward into the lower lid, with vertical reanchoring of the inferior arc of the orbicularis muscle.

Vertical reanchoring of the orbicularis muscle is demonstrated, with recruitment of skin into the lower lid. Reanchoring the orbicularis also acts as the supportive sling for lower lid repositioning. The vector of orbicularis anchoring is performed in accordance with eye prominence. A more vertical vector of fixation, to the temporal fascia and periosteum, is used when more skin recruitment is required and in patients with more prominent eyes.

Orbicularis reanchoring is usually combined with canthal reanchoring, as described earlier. One may use a more limited orbicularis dissection and reanchoring in milder cases of lower lid retraction in which the skin shortage is not severe.

This woman exhibits mild retraction and skin shortage in the lower lid before and after recruitment using vertical reanchoring of the orbicularis muscle. In patients with increased or severe skin deficiency, extensive vertical repositioning of the inferior arc of the orbicularis may be needed to recruit greater amounts of skin upward into the lower lid, which usually eliminates the need for skin grafts in these patients.

Moderate retraction and skin shortage in the lid is evident in this patient both before and after recruitment using vertical reanchoring of the orbicularis muscle.

This patient has retraction and skin shortage in the left lower lid before and after recruitment using vertical reanchoring of the orbicularis muscle. In the past this patient would have required a skin graft for correction.

Spacers

The use of spacer inserts in the lower lid posterior lamella in patients undergoing primary surgery was described earlier in this chapter. The same procedure is used in patients with secondary lower lid retraction for corrective surgery. Spacer inserts in the lower lid (AlloDerm, ear cartilage, autogenous dermis) lengthen the posterior lamella and elevate the lower lid margin upward in patients with significant eye prominence (defined as 19 mm or more as measured by an exophthalmometer).

On the left, this woman is shown after lower lid blepharoplasty with extremely prominent eyes and moderately severe lower lid retraction. She required transcutaneous placement of spacer material in the posterior lamella of the lower lid with vertical recruitment of skin. Her postoperative result is shown on the right.

Even in patients with normal eye prominence with significant middle lamella scarring, spacers can help prevent postrepair contracture of scar tissue. On occasion, in reconstructive patients who do not require skin recruitment, the spacer may be placed internally without a transcutaneous approach.

The position of the spacer material is shown after internal placement in the lower lid. Spacers are usually needed in patients with very prominent eyes or those who have retraction from scarring of the middle lamella. In more severe cases, transcutaneous spacer placement may be required, in conjunction with orbicularis elevation for skin recruitment.

Complications of Autologous Fat Injections

Correction of aging lower lids and blending of the lid-cheek junction with autologous fat microinjections is becoming increasingly popular. Although some of the results have been impressive, we have seen a number of patients in whom the fat has been injected superficially, subcutaneously, or in the superficial layers of the orbicularis, leading to unsightly “beading” of the lower lid. These problems may be difficult to correct. The fat may be removed through the transconjunctival approach. As with any complication or problem, avoiding the problem from the outset is preferable to correction. Injection of the fat deep and directly over the periosteum is best to prevent postoperative irregularities and beading.

Treatment Options

Steroid injections may induce atrophy of the injected fat but are not always successful and carry the risk of skin changes and telangiectasia. Suctioning the fat with a fine needle is not uniformly successful. Injections of phosphatidylcholine and deoxycholine may result in resolution but such treatments have not been established. Surgical removal of the injected fat is the treatment of choice. The fat may be accessed through the conjunctiva, transcutaneously, or with a skin-muscle flap.

This woman had undergone autologous fat injections into the lower lid in an attempt to improve lower lid aging and descent of the lower lid–cheek junction. The excess superficially injected fat is quite evident. She also had bilateral lid retraction that was worse on the right than on the left.

Through the skin-muscle flap approach, the autologous fat within and superficial to the orbicularis muscle was easily located. The excess fat was dissected and removed. After all the excess fat was successfully removed, the orbicularis was mobilized and redraped.

Preoperative and postoperative views demonstrate improved lid appearance, more effective lid-cheek junction blending after removal of the injected fat, orbicularis muscle flap redraping, and canthopexy. The split view shows the improvement on the left side.

AESTHETIC GOALS IN THE UPPER LID

Spacing and Definition

Harmony of positioning with the upper lid and brow is of the utmost importance for patient satisfaction. It is important to produce the desired contours of the eyelid crease, the position of the eyelid margin, and even the brow spacing the patient desires. In practice, the desired result can be highly individualized, and the same fixed formula of spacing and positioning should not be arbitrarily used in all patients. This aspect of the proposed surgery should be discussed with the patient in detail for surgical planning to determine the patient's preferences and to avoid dissatisfaction when the result does not meet the patient's aesthetic goals.

After upper lid blepharoplasty with a very high upper lid crease and a very wide “eye shadow space,” this woman was unhappy because her appearance was too dramatic a change from her previous appearance. Her previous eyelid spacing is seen on the left, before the upper lid blepharoplasty had been performed.

Old photographs of the patient may be helpful in defining goals and the amount of defined eye shadow space the patient desires. Preoperative planning is even more important in Asian patients, who may vary in their desire for a “Westernized” look. It is important to recognize the tendency for the upper crease to migrate upward in patients with prominent eyes, and this should be pointed out to the patient.

Position of Upper Lid Margin

It is important to make note of the relationship of the upper lid margin to the pupil of the eye. How much color of the iris can be seen above the pupil? Compensatory brow arching or severe dermatochalasis may mask preexisting ptosis. True upper lid ptosis should be pointed out and discussed before surgery.

Prevention of Upper Blepharoplasty Complications

An important functional goal in upper blepharoplasty is that surgery should not compromise the strength and velocity of upper lid closure. Among patients who have poor eye moisture or reduced ocular motility, any lagophthalmos, however subtle, may cause distressing symptoms. Severe lagophthalmos in any patient can cause damage or disability of the eye as a result of corneal exposure.

Differences Between the Nasal and Temporal Upper Lid

Lagophthalmos in the nasal half of the upper eyelid is less well tolerated than lagophthalmos in the temporal half of the upper lid, either with symptoms or corneal changes. Cautious skin removal in the nasal half of the upper lid is advised. In some patients, skin laxity and unwanted fullness in this area can be improved by brow elevation and fat removal alone. Minimizing skin removal in the nasal half of the upper lid reduces the chance of symptomatic lagophthalmos.

Considerations in the nasal half of the upper lid and the temporal half of the upper lid are illustrated with regard to problems, pitfalls, and corrective procedures. Stiffness in the outer half of the upper lid is much better tolerated by the eye, so more complete removal of redundant skin may be carried out in this area. Lateral brow stability influences the amount of residual folding that may occur in the lateral upper lid postoperatively. To avoid annoying residual folds in this area and ensure a continuous space with the pretarsal area, we recommend stabilizing the lateral brow, either with a temporal lift or an internal browpexy. It is our practice to include a transblepharoplasty internal browpexy with almost every upper lid blepharoplasty.

Techniques of Upper Lid Blepharoplasty

Design of the Upper Blepharoplasty Skin Excision

The amount of skin that is surgically removed in the upper lid is not as important as the skin that remains postoperatively in the lid. The general placement of skin markings for excision is shown below.

This illustration shows the recommended excision of skin and underlying orbicularis and septum in the so-called open-sky approach to upper lid blepharoplasty. This approach emphasizes the principle that the most important consideration in the upper lid is how much skin is left behind rather than how much is excised.

One should minimize the excision of skin in the nasal half of the eyelid, because, as previously described, nasal lagophthalmos causes the most severe exposure. Excessive laxity in this area can be addressed with cautious skin excision, but correction of any brow laxity may reduce the amount of skin excision needed. The open-sky technique, with removal of skin and the underlying orbicularis and septum, is safer and gives the surgeon more options at the time of upper blepharoplasty surgery. Debulking the subcutaneous tissue produces less skin tightness on closure, and the added exposure provided allows access to the levator aponeurosis if ptosis surgery is required. One should avoid creating scarring in any orbicularis or septal layers that remain. Postoperative upper lid lagophthalmos from middle lamella scarring is most difficult to correct. The open-sky technique of upper blepharoplasty may require excision of the orbicularis and septum near the insertion of the levator aponeurosis, which may in some cases, particularly in patients who are predisposed to ptosis, weaken the levator aponeurotic insertion and produce postoperative ptosis.

Aponeurotic Safety Stitch

When upper blepharoplasty is performed, even in patients in whom no ptosis is present, plication of the upper pretarsal skin edge to the aponeurosis is a safeguard against levator dehiscence and controls the position of the upper crease. This is easily performed with the open-sky technique.

This illustration demonstrates the “safety stitch” used in conjunction with the open-sky technique to ensure levator aponeurosis attachments and to control the position of the upper lid crease.

Surgical images show placement of the safety stitch using 6-0 Vicryl. The stitch is placed through the skin at the upper edge of the incision and then into the levator aponeurosis. The suture is tightened, but not enough to cause eyelid gapping.

Brow Treatment

For significant eyebrow laxity, the surgeon should use a formal brow procedure, endoscopic forehead lift, or temporal lift for stabilization of the eyebrow/eyelash distance. In milder cases, the problem can be addressed in the lateral upper eyelid with transblepharoplasty internal browpexy. Fixation of the subbrow fat pad (retroorbicularis fat) to the deep temporal fascia with permanent sutures can reduce or eliminate brow sagging and avoid residual lateral folding in many patients.

The steps in the internal browpexy are illustrated. On the left, the area to be undermined in the preperiosteal plane is shown, and on the right, the exposure of the deep temporal fascia is shown.

In these images of internal browpexy, the image on the left shows the fixing suture being placed in the deep temporal fascia. The image on the right shows insertion of the suture in the retroorbicularis oculi fat at the level of the inferior edge of the brow. The vector of pull is usually in an upward/outward direction.

This patient is seen after upper lid blepharoplasty with an internal browpexy. On the left, the temporal half of the upper lid and tail of the brow are shown preoperatively. The desired postoperative result is shown on the right. This includes firm support of the tail of the brow, an upper lid crease, and an eye shadow space that extends past the canthal angle without residual skin folds.

Prevention of Ptosis

Correction of Coexistent Ptosis

In a patient requesting upper lid blepharoplasty, the usual cause of ptosis is a dehiscence of the levator aponeurosis. Aponeurotic repair can easily be performed through the upper lid blepharoplasty incision if surgical exposure is adequate. The open-sky approach to upper lid blepharoplasty provides adequate exposure of the levator muscle and aponeurosis so that repair can be performed in these patients.

Mechanism and Cause of Levator Dehiscence

Levator aponeurotic attachments to the upper lid travel to the anterior surface of the tarsal plate and to eyelid skin in the crease area. With levator dehiscence, because of thinning and disinsertion, the aponeurotic portion of the levator pulls away from its tarsal attachments and with its retraction the upper lid becomes ptotic.

This illustration shows the normal levator on the left with its aponeurosis sending attachments to the anterior surface of the tarsal plate and to the eyelid skin to form the upper lid crease. With dehiscence of the levator aponeurosis, as seen on the right, the aponeurotic attachments dehisce, allowing the lid to relax downward and causing ptosis combined with upward pulling of the skin attachments; this produces a visibly high upper lid crease (unless there is severe dermatochalasis).

Persistent aponeurotic attachments to the upper eyelid skin may cause a characteristically high upper lid crease, depending on the fullness of the upper lid. In susceptible individuals, surgical trauma or the postoperative edema of surgery may cause levator dehiscence, resulting in postoperative ptosis, as seen in this patient.

Correction of Ptosis

Ptosis repair can be performed in patients with preexisting ptosis while they are undergoing upper blepharoplasty, or it can be performed to repair ptosis, which may occur as a complication. The technique for ptosis repair in these patients is anatomic reattachment of the levator aponeurosis. A single suture is used for the attachment of the tarsal plate to the musculoaponeurotic junction of the levator. Other anatomic changes that commonly occur with age must be taken into account for proper contouring of the lid. With the use of the single-suture repair (double-armed 6-0 silk), suture placement must be in a vertical line with the midpupil near the superior edge of the tarsal plate.

The normal levator attachments and landmarks are illustrated. In most adults, because of dehiscence of nasal attachments of the lid, there is a lateral shift of the tarsal plate. To produce the desired contour in the upper lid, the required placement of the single lifting suture used in acquired ptosis (placed in the tarsus near the superior edge of the tarsal plate) must be in line with the pupil.

Suture alignment with the apex of the upper tarsal curve cannot be used because in patients of this age there is a lateral shift of the tarsus.

Placement of the lifting suture in the musculoaponeurotic junction of the levator muscle is illustrated. After suture placement in the tarsal plate, the suture arms are brought under the levator aponeurosis; the edge of the dehiscenced aponeurosis has been dissected free of Müller's muscle, and the suture is placed through the levator at the musculoaponeurotic junction.

In cases of bilateral ptosis, the anatomic placement of sutures should be symmetrical. Placement of the suture for ptosis at the junction of the muscular portion of the levator and its aponeurosis is illustrated.

This patient had bilateral levator dehiscence. She is seen after blepharoplasty and bilateral aponeurotic repair using the technique described. No secondary surgery for symmetry was necessary in this patient.

After suture placement and temporary tightening, adjustments should be made to ensure symmetry (in cases in which the ptosis is bilateral). This can be done under general anesthesia without patient cooperation. After the suture has been tightened, the intraoperative gapping of the lid fissure that occurs should be even between the lids. An additional test—the “spring-back test”—is needed to help achieve symmetry. When one of the upper lids is pulled closed and quickly released, the velocity of upward spring should be the same in each eye. If these adjustments are observed, in most cases there will be postoperative symmetry in the ptosis correction. Patients with unilateral ptosis may require postoperative adjustments.

Complications in the Upper Lid and Treatment of Postoperative Lagophthalmos

Poor upper lid closure after blepharoplasty can be attributed to these causes:

- Surgically induced upper lid stiffness
- Patients without stiffness, because of loss of lateral canthal anchoring
- Poor closure mechanics

Intrinsic upper lid stiffness can result from excessive skin removal causing skin shortage or from internal scarring.

The three possible areas of restriction are shown; these may cause lagophthalmos in the upper lid after surgery. In the top figure, poor closure resulting from a shortage of skin is represented, which, if it is not overcome by firm canthal reanchoring, will require skin replacement. In addition to a skin shortage, patients may have scarring of the middle lamella with adhesions of the orbicularis and septum to the superior orbital rim, as seen in the middle figure. These adhesions must be separated to restore closure of the upper lid. The most severe situation occurs when the levator is bound to structures at the superior orbital rim, as seen in the image on the far right. The levator adhesions can be released, but it is common to produce ptosis post-operatively in these patients.

Corneal symptoms are more severe, with lagophthalmos occurring in the nasal half of the upper lid than in the lateral half, as mentioned earlier. The lateral half of the eye seems to be more forgiving of lagophthalmos because of lateral brow laxity.

Scarring in the internal structures of the upper lid, orbital septum, and fat pads (middle lamella scarring) produces lagophthalmos, which is more difficult to correct. Care should be taken to avoid scarring of the middle lamella by inappropriate cautery, particularly if the tissue is to be left behind in the upper lid. The orbicularis and orbital septum are best treated with excision using the open-sky technique as described earlier; however, one may leave varying amounts of orbicularis to avoid excessive crease formation, if indicated.

Approach to the Treatment of Upper Lid Lagophthalmos

Surgery in the upper lid directly to correct lagophthalmos after blepharoplasty can be problematic, because it usually requires skin grafts and can be upsetting to the patient who is undergoing a cosmetic procedure. Direct surgical intervention is restricted to patients who have vision-threatening problems and in whom all else has

failed. In patients with poor eyelid closure after blepharoplasty, every attempt should be made to relieve the problem by first attempting corrective surgery in the lower lid. It is important to ensure that canthal anchoring is firm, because deficiencies in that area can significantly contribute to poor eyelid closure mechanics. When faced with definite upper lid tethering from skin shortage or internal scarring, the surgeon can reposition the lid upward by the methods described in the previous section to help reduce the exposure by narrowing the eyelid separation. This approach often precludes the need for direct surgery on the upper lids. Improvement in eyelid closure mechanics, preferably by drill-hole fixation, as described earlier, can overcome some of the resistance of a stiff upper lid and improve upper lid closure. This is particularly true if lagophthalmos is accompanied by the fish-mouthing effect, a sure sign of inadequate canthal attachment.

This woman is shown (*left*) after blepharoplasty with a reasonably normal eye fissure appearance but poor eyelid closure as a result of weakened canthal anchoring. On the right, the same patient is shown immediately after firm reanchoring of the lateral canthus with improved eyelid closure. The double drill-hole technique is indicated in such a patient if the eye is prominent.

This patient shows adequate restoration of eyelid closure with lower lid repositioning and canthal anchoring, even in the face of significant upper lid stiffness. She presented with retraction of the lower lid and lagophthalmos of the upper lids after blepharoplasty and laser resurfacing. Poor closure in the upper lids was caused by a skin shortage as well as canthal dehiscence, resulting in poor eyelid closure mechanics. After bilateral canthal anchoring with the use of drill-hole fixation of the canthal tendons, her situation is much improved. Lower lid repositioning was also performed with recruitment of skin, with orbicularis vertical reanchoring and spacer implants of autogenous dermis. No skin grafts were placed in the upper lid. Closure of the upper lid was restored by firm reanchoring of the lateral canthus and repositioning of the lower lid only. The upper lid stiffness resulting from the presence of a skin shortage was overcome by strengthening the eyelid closure mechanics by means of canthal reanchoring.

Only after restoring lower lid position and improving closure mechanics should one resort to direct surgery to the upper lid. However, some patients, because of the severity of upper lid stiffness from a skin shortage or internal scarring, may be improved by the approaches described but will still have inadequate closure and corneal exposure problems. In these patients, skin grafts to the upper lid are needed.

The proper placement of a full-thickness skin graft in the upper lid is illustrated for correction of lagophthalmos resulting from skin shortage. In most cases the skin can be released with an incision just above the lashes, allowing the skin edge to retract upward to the crease area. The graft can then be placed in the space between the lashes and the crease to maintain a standard eye shadow space and crease position.

This patient is seen after blepharoplasty (*left*) with extreme upper and lower lid retraction, poor eyelid closure, and corneal damage from exposure. The skin shortage in the upper eyelids was profound. The position of the lower lids was improved, with drill-hole canthal anchoring, but exposure problems were not totally eliminated. Upper lid skin grafting is needed. When skin grafts are indicated, they should be positioned so as not to alter the crease formation of the upper lid or disturb the aesthetic contours of the upper lid. Graft placement should not span the crease area, and grafts are best placed between the lashes and the crease or above the crease if a

second graft is needed. After the placement of upper lid skin grafts (*right*), this patient was able to achieve more normal eyelid closure. Middle lamella scarring was also encountered in this patient, and lysis of adhesions from the lid to the superior orbital rim was required.

In some cases, even after release of the skin between the lashes and the crease, the upper lid may still show resistance to closure. This is a sign of internal, middle lamella, or septal scarring, which requires release before the graft is placed. The patient on p. 1062 is seen after drill-hole canthal anchoring, a reconstructive cheek lift with autogenous spacers, and full-thickness skin grafts to the pretarsal area of her upper lids. She also had internal scar tissue adhesions in the middle lamella that required release.

Upper Lid Crease: Sulcus Abnormalities

The most common sulcus abnormality that causes distress to the patient is an excessively high upper lid crease or a hollowed-out appearance in the upper lid. Overzealous removal of fat from the upper lid in patients who are not used to a deep crease or do not want a high crease is a common cause of this problem and can produce an unwanted deep-set look. Even a standard amount of fat removal, if the eye is very prominent, can produce an unwanted high crease. Excessive removal of fat in the nasal third of the upper lid may produce a peaking of the crease in that area producing an “A-frame” deformity. Another uncommon but definitely occurring complication of aggressive fat removal in this area is injury to the superior oblique tendon, either by direct trauma or cauterization of bleeding in that area.

Restoration of fullness in these areas is difficult. The most fortuitous situation encountered is when there is still available preaponeurotic fat present in the upper lid that can be brought out and sutured forward to the crease area in the upper lid. An open incision through the orbital septum is necessary. This approach may not be available in many patients.

Attachment of dermis fat strips to the arcus marginalis for augmentation in this area has been helpful in some patients, but the possibility of tethering upper lid movement always exists if secondary fibrosis occurs and affects the levator muscle. Direct grafts that may adhere to the levator are ill advised.

An undesirable high upper lid crease can be seen in some patients with early dehiscence of the levator aponeurosis in which retraction of the aponeurotic skin crease attachments precedes the actual ptosis. In these patients, conservative repair of the levator aponeurosis may restore upper lid crease position and ward off an incipient true ptosis.

Clinical Caveats

Patients who have suspicious symptomatology or unusual findings on an eye examination, and those with a history of eye problems, should be evaluated by means of slit-lamp examination, tear tests, or consultation with an ophthalmologist.

The anatomic classification of the orbicularis into orbital, preseptal, and pretarsal orbicularis is convenient for surgical labeling, but a functional classification of the orbicularis into an inner canthal orbicularis and an extracanthal orbicularis should be adopted for better understanding of eyelid function.

Loss of eyelid innervation from the buccal branch of the facial nerve to the inner canthal area will cause profound changes in eyelid function, with reduction or absence of eyelid blinking, poor lower lid tone and position, and a weakening of the lacrimal pump mechanism causing tearing.

Firm anchoring laterally is needed for counterpull against canthal contracture to convert the vector of the blink movement into a vertical one for proper eyelid closure.

The skeletonization of the orbital rim area associated with age is a major contributor to the aging appearance in the midface area. Surgery that fails to address the eyelid and cheek area as an aesthetic unit falls short of producing a true reversal of aging changes in this area.

In persons with prominent eyes, a downsliding of the lower lid, scleral show, and enlargement of the lateral scleral triangle may occur. Proper canthal anchoring restores a more youthful look to the eye fissure by changing the shape of the fissure.

It has been shown mathematically that protrusion of the eye against the eyelid affects the shape of the eye fissure.

In cases of lower lid laxity, reinforcement with shortening of the lower lid is necessary.

In patients who have laxity of the tarsoligamentous sling, tightening only the orbicularis muscle will not correct internal lower lid laxity and can produce outward buckling of the lid because of the redundancy in the posterior lamella. Tightening of the tarsoligamentous sling itself must be performed.

The position of the lower lid changes in response to traction at the lateral canthus.

If skin shortage is a significant factor in lower lid retraction, vertical canthal anchoring of the inferior arc of the orbicularis muscle will recruit skin upward into the lower lid and will, in most cases, correct retraction without the use of a skin graft.

Spacer inserts in the lower lid (AlloDerm, ear cartilage, autogenous dermis) lengthen the posterior lamella and elevate the lower lid margin upward in patients with significant eye prominence.

Harmony of positioning with the upper lid and brow is of the utmost importance in terms of patient satisfaction.

It is essential to note the relationship of the upper lid margin to the pupil of the eye.

An important functional goal in upper blepharoplasty is that surgery should not compromise the strength and velocity of upper lid closure.

Lagophthalmos in the nasal half of the upper eyelid is not as well tolerated as lagophthalmos in the temporal half of the upper lid, either with symptoms or corneal changes.

When upper blepharoplasty is performed, even in patients in whom no ptosis is present, plication of the upper pretarsal skin edge to the aponeurosis is a safeguard against levator dehiscence and controls the position of the upper crease. This is easily performed with the open-sky technique.

Only after restoring lower lid position and improving closure mechanics should one resort to direct surgery on the upper lid.

In some cases, even after the release of the skin between the lashes and the crease, the upper lid may still show resistance to closure. This is a sign of internal, middle lamella, or septal scarring, which requires release before the graft is placed.

Annotated Bibliography

Codner MA, Wolfli JN, Anzarut A. Primary transcutaneous lower blepharoplasty with routine lateral canthal support: a comprehensive 10-year review. *Plast Reconstr Surg* 121:241-250, 2008.

This study reviewed the outcome of a surgeon's 10-year experience with primary lower transcutaneous blepharoplasty and lateral canthal support consisting of canthopexy, canthoplasty, and orbicularis suspension. The authors conclude that lateral canthal support should be considered a routine component of lower transcutaneous blepharoplasty to obtain the desired aesthetic result and maintain the natural appearance of the eyelid shape, and that the associated complication rate is acceptable.

Malbouisson JM, Baccega A, Cruz AA. The geometrical basis of eyelid contour. *Ophthalmol Plast Reconstr Surg* 16:427-431, 2000.

The authors derived a two-dimensional, frontal-view model of eyelid contour. After performing an observational study of palpebral fissure images from 110 normal subjects, they concluded that the parabolic shape of the upper ciliated contour seen in two-dimensional images can be justified geometrically in a simple way, allowing a precise quantification of its shape. The same was not true for the lower eyelid. The parabolic shape of the upper eyelid can be demonstrated, using the Taylor series, to be a close approximation of the arc of a circle.

McCord CD. The correction of lower lid malposition following lower blepharoplasty. *Plast Reconstr Surg* 103:1036-1039, 1999.

Lower eyelid malposition is the most common complication after lower eyelid blepharoplasty. When this problem occurs, it is imperative to correct the malposition by the most efficient method. The author presents methods for correcting minor as well as severe cases.

McCord CD, Boswell CB, Hester TR. Lateral canthal anchoring. *Plast Reconstr Surg* 112:222-237, 2003.

Any surgeon performing cosmetic or reconstructive surgery procedures on the lower lid or midface through the lower lid should be comfortable with canthal anchoring procedures. This article discusses the principles involved in canthal support for patients undergoing cosmetic and reconstructive surgery, variations in surgical techniques required to perform canthal anchoring in a variety of patients, the significance and techniques of canthal anchoring (canthoplasty and canthopexy) as they relate to cosmetic and reconstructive lower lid surgery, and the effect of canthal anchoring on the function of the upper and lower lids and eyelid fissure shape.

Pacella SJ, Codner MA. Minor complications after blepharoplasty: dry eyes, chemosis, granulomas, ptosis, and scleral show. *Plast Reconstr Surg* 125:709-718, 2010.

The authors discuss several of the most common minor complications, including hematoma, dry-eye syndrome, infections, atypical lesions, lid malposition, and scarring. In addition, preoperative assessment of risk factors, treatment, and management of these minor complications are presented.

Putterman AM. Regarding comprehensive management of chemosis following cosmetic lower blepharoplasty. *Plast Reconstr Surg* 124:313-314, 2009.

The author reports patient finger compression as an effective treatment method for conjunctival chemosis.

Weinfeld AB, Burke R, Codner MA. The comprehensive management of chemosis following cosmetic lower blepharoplasty. *Plast Reconstr Surg* 122:579-586, 2008.

This article focuses on chemosis associated with cosmetic lower blepharoplasty. The cause is multifactorial and includes exposure, periorbital edema, and postoperative lymphatic dysfunction. The incidence of chemosis was 11.5 percent of the 312 primary bilateral lower transcutaneous blepharoplasties reviewed. Chemosis presented intraoperatively or up to 1 week postoperatively; the median duration was 4 weeks, with a range from 1 to 12 weeks. Associated etiologic factors included conjunctival exposure, periorbital and facial edema, and lymphatic dysfunction. Successful treatment existed along a continuum from liberal lubrication to ophthalmic steroid preparations and ocular decongestants to eye-patching to minor surgical procedures such as drainage conjunctivotomy and temporary tarsorrhaphy. In all cases, chemosis ultimately resolved.

PART VII

MIDFACIAL REJUVENATION

This page intentionally left blank

CHAPTER 35

Clinical Decision-Making in the Midface

FOAD NAHAI

For most individuals, aging of the lower lid and midface is intrinsically interrelated; therefore the best treatment options rejuvenate both areas. There are many surgical and nonsurgical options for rejuvenation of the midface. The role of injectable fillers and fat continues to evolve but for most of us, rejuvenation of the midface is a surgical procedure.

Restoration of volume and repositioning of the malar fat pad is the foundation of midface rejuvenation. Approaches for surgical elevation of the malar fat pad include the following:

- Temporal approach
- Transpalpebral approach
- Standard or modified face-lift approach

Although all of these approaches elevate the midface, with the exception of the transpalpebral approach, the vector is usually diagonal. A true vertical vector of elevation is achieved only through the lower lid.

Temporal Approach

The temporal approach entails an incision in the temporal area and endoscopic dissection into the midface. Elevation and fixation of the midface are accomplished through long suspension sutures or fixation devices, such as the Endotine device (see Chapter 38).

The advantage of the temporal approach is that the scar is well hidden within the hair. It is effective for elevating the midface (malar fat pad) and affords some blending of the lid-cheek junction. However, it only produces a diagonal vector for elevation of the midface and does not address aging of the lower lid or of the lower face. The temporal approach is best for individuals with isolated midface aging. It can be combined with blepharoplasty and a lower face lift in individuals with panfacial aging.

Transpalpebral Approach

This approach affords not only a diagonal vector but also the only true vertical vector for elevation of the midface, combined with lower lid rejuvenation. The major concern about this approach involves lower lid retraction. The approach can be modified to minimize the risk.

If manipulation of the lower eyelid fat is planned, a full-length skin-muscle incision is made and the skin-muscle flap elevated for access to the periorbital fat. The risk of lid retraction is minimized through the routine application of lid-anchoring techniques and a diagonal vector on the orbicularis oculi muscle to add extra support to the lower lid in addition to the aesthetic improvement.

Fixation vectors

If fat manipulation is not planned, a very limited incision is made laterally in the orbicularis, and midface mobilization is accomplished either with an endoscope, a headlight, or a small lighted Aufricht retractor. This alternative approach in which the orbicularis is not divided along the entire length of the lid carries a lower risk of lid retraction while offering the same vertical and diagonal vectors as the full open approach.

Face-Lift Incisions

Through the standard face-lift incision or the modified prehairline incision, the SMAS is easily accessed and can be manipulated to elevate the midface.

Surgical Options

The high SMAS technique
The extended MACS lift
SMASectomy and SMAS plication

The High SMAS Technique

The incision in the SMAS at or above the level of the zygomatic arch combined with adequate mobilization of the SMAS facilitates effective elevation of the midface and malar fat pad with blending of the lid-cheek junction in a diagonal direction. When performed in isolation, it is not effective in dealing with the aging lower lid; it does, however, reliably rejuvenate the midface, lower face, and jaw line.

The Extended MACS Lift

The third and highest of the purse-string sutures described with the extended MACS-lift (see Chapter 42) effectively and diagonally elevates the midface with some blending of the lid-cheek junction. Tonnard and Verpaele combine this procedure with a skin pinch blepharoplasty to rejuvenate the aging lower lid.

SMASectomy

The upper part of the diagonal SMAS, when excised and sutured or plicated, does effectively elevate the midface with some blending of the lid-cheek junction. To fully rejuvenate the lower eyelid, the surgeon must perform a blepharoplasty to deal with the eyelid, skin, and orbicularis muscle.

Choosing the Best Option

For patients who require a blepharoplasty to address the skin, orbicularis muscle, and fat pads, the transpalpebral route offers midface lifting and full rejuvenation of the lower lid. If the lower lid rejuvenation requires only lid-cheek blending without extensive skin, muscle, or fat manipulation, the temporal and face-lift approaches are suitable options.

Choosing the Best Option						
	Vectors		Rejuvenation/Lift			
	Vertical	Diagonal	Eyelids	Midface	Lower Face	Jaw Line
Transpalpebral	++++	++++	++++	++++	—	—
Transtemporal	+	++++	++	+++	+	—
Face-lift approach	+	++++	++	++++	+++	+++

Although the transpalpebral approach affords a more direct midface lift with unlimited opportunities for eyelid rejuvenation, it is also the only approach that poses a risk of eyelid retraction and its consequences. Some surgeons think that this risk is not adequately offset by the advantages. The eyelid approach also involves longer recovery, as does any complex procedure in this area.

Alternative approaches involving the percutaneous insertion of barbed sutures have been advocated, but their efficacy and long-term outcomes remain in question.

CHAPTER 36

Cheek Lift

JOEL J. FELDMAN

My approach to facial rejuvenation is a regional one. Out of 100 patients, I will perform a cheek lift without a neck lift in about 20, because these patients either do not need or do not want a neck lift. A good many will have already had the neck tended to one way or another, and now it is just the cheek that is in need of attention. Others simply find that for the first time a nasolabial or labiomandibular fold has become unacceptable, while the signs of aging in the neck still remain tolerable. Then there are others with only a small amount of soft tissue laxity in the submental neck that might well snug up nicely to an *isolated cheek lift* if it is done well.

On the other hand, in approximately 50 of every 100 patients that I operate on for facial rejuvenation, I will perform a neck lift without a cheek lift—the so-called *isolated neck lift*—because, in the same way, these patients do not need or do not want a cheek lift. Then in the remaining 30 patients, I will do a combined cheek lift and neck lift—a more conventional undertaking—commonly referred to as a *face lift*. In this chapter I will describe my approach to cheek-lifting—either done alone or as part of the cheek-neck combination. Either way, the surgical maneuvers I employ are the same. I have not included management of the neck in this chapter, because that material has been published in detail elsewhere.

Brief mention should be made here regarding the difference between a *cheek lift*, a *midcheek lift*, and a *lower cheek lift*. A *cheek lift* is, at its best, capable of correcting soft tissue laxity in all areas of the face—upper, central, medial, lower, and lateral. In that regard, a more accurate term for the subject of this chapter might well be the *complete cheek lift*. It is, of course, performed through a preauricular incision. The *midcheek lift*, on the other hand, is usually performed through a lower eyelid incision, and its surgical objectives are considerably more modest—namely, a resuspension of the slumping perimalar tissues in the area of the lid-cheek junction and upper nasolabial fold. That procedure would not be expected to produce very much, if any, improvement beyond the upper cheek. The *lower cheek lift*, as I envision it, is aimed primarily at improving the lower nasolabial fold and labiomandibular fold. It is often combined with a neck lift in patients who do not want or do not need an accessory lower eyelid lift or temporal lift (discussed later), so in those patients, I may do a little less flap undermining in the uppermost areas of the cheek.

Evolution of Technique

The Extensively Undermined Point-Tensioned Subcutaneous Cheek Lift

I completed my plastic surgery residency in 1976, the year that Mitz and Peyronie published their seminal paper on the anatomy of the SMAS, and only a few years after Skoog of Sweden had dazzled the attendees at the 1973 Baker-Gordon Symposium in Miami with a live demonstration of his new and revolutionary sub-SMAS

face-lift operation. Those two events produced a seismic change in the basic assumptions of face-lifting, and the old-fashioned subcutaneous flap technique that I had been taught became more or less passé. Most plastic surgeons thought that an undermining and lifting of the SMAS would make for a better face lift.

Soon, however, there were two kinds of SMAS lift procedures to choose from—a two-flap model and a one-flap model. The two-flap method employed a separate skin flap and a separate SMAS flap, each carrying about half the thickness of the subcutaneous fat. The assumption was that it was better to lift the malar and jowl fat attached to the SMAS in a more vertical direction than the skin with its attached fat, which was best lifted along the traditional vector, perpendicular to the nasolabial crease. That concept made sense to me, so a few years after starting out in practice, I decided to try the two-flap SMAS lift technique. I tried out several versions over a period of several years and found that with all of them, a thin SMAS flap often tore easily when I tried to suture it under tension. In addition, a thin skin flap in a thin patient at times had a precarious blood supply, particularly in patients who smoked. What's more, having two slightly different vectors of lift, one for the skin flap and one for the SMAS-fat flap, produced little if any noticeable benefit in my hands.

Then I tried the one-flap SMAS lift procedure, better known as the *deep plane face lift*, a technique developed by Hamra. I really liked that operation. The sub-SMAS dissection plane was nice and dry, with very little intraoperative bleeding and a very low incidence of postoperative hematoma, even after I had done an extensive medial undermining, which I learned was important in terms of consistently producing a high-quality result. In my modified version of the deep plane lift, I started the deep plane dissection 1.5 cm preauricularly. Then, along the lateral border of the zygomaticus major muscle in the upper cheek, where the SMAS becomes the invisible epimysium of that muscle, I entered the subcutaneous plane again to continue the dissection almost to the sidewall of the nose in the upper medial cheek and over to the nasolabial crease in the central medial cheek. In the lower half of the cheek, after releasing the sub-SMAS masseteric-cutaneous ligaments, I would break through the medial SMAS to enter the subcutaneous plane and then continue the dissection over to the corner of the mouth and the side of the chin. That change of tissue planes from superficial to deep and then back to superficial left the cheek flap with only a narrow jawline-based peninsula of SMAS on its underside. In reality, my deep plane lift had in large part become a subcutaneous lift.

However, the deep plane flap was thicker than the usual subcutaneous flap, providing a robust blood supply that allowed me to anchor it safely at multiple points under considerable tension—which I did—because I had become increasingly appreciative of the importance of holding the well-mobilized flap securely in the lifted position during the 6 to 8 weeks needed for solid healing to begin. Overall, my results with this modified deep plane lift were quite good, so I continued to use it in most cases for more than 20 years.

During that time, however, I also occasionally performed a subcutaneous cheek lift—mostly on patients with chubby cheeks on whom I wanted a wide-open access for thinning of the subcutaneous fat and in patients who had had a previous sub-SMAS face lift and who at the time of a secondary lift were found to have a deep plane that was too scarred or distorted to allow me to continue safely at that level. But unlike the subcutaneous lift that I had done many years earlier, the subcutaneous lift that I was by then using incorporated three elements that I had learned from doing the deep plane lift were critical to a first-rate result.

One of those important factors was a very extensive flap undermining, as seen here, which was done to release all of the skin and fat-retaining ligaments and filaments in the medial cheek that might inhibit the unrolling of a nasolabial fold or labio-mandibular fold (*marked in red and green in the illustration below*).

The second important factor needed for a consistently good result using the subcutaneous cheek lift was a very secure fixation of the lifted flap to counteract, as much as possible, both the *stress relaxation* and *viscoelastic creep* of stretched skin, and the pull of gravity, which urged the flap to slide downhill along a yet-to-heal dissection plane.

The third important element was having a single point of flap fixation situated precisely at the convergence of all the important vectors of lift required for a complete cheek lift—the vectors needed for improvement of the upper and lower nasolabial fold, the labiomandibular fold, the jowl, and the jawline. That specific fixation point was located at the immobile periosteum over the lateral zygomatic arch just in front of the upper ear (*circled X*)—a particularly safe place for a deep anchoring suture, well behind the frontal branches of the facial nerve. At that one point of flap fixation, a controlled amount of tension could be applied to the body of the flap—enough to hold the flap up securely—but not so much that it would compromise the blood supply of this skin flap that has a less-robust blood supply than the deep plane flap. Equally important, none of the tension on the flap itself was transferred to the skin incision line closure, so there was no forward traction on the ear, earlobe, or tragus, and the incision scars were able to heal kindly. In contradistinction to what some plastic surgery colleagues imagined, I found that placing a moderate amount of tension on the cheek skin flap did not at all produce a flattening of the facial plane.

After having acquired considerable experience using both the extensively undermined point-tensioned subcutaneous lift and the deep plane lift, a few years ago I thought it would be interesting to compare my results between those two methods. I looked at hundreds of preoperative and postoperative photographs of patients I had operated on using one method or the other, and although the analysis was far from scientific in its methodology, I came away with an unambiguous conclusion: at 1 or more years after surgery, I could not tell the difference between the results in the two groups of patients.

For example, the patient above and the one shown on p. 1085 are shown before and 3 years after surgery. The first patient (*above*) had a subcutaneous lift, and the second patient (*p. 1085*) had a deep plane lift. To my eye, the results are of equal quality.

However, the two procedures did differ in some other ways. Compared with the deep plane lift, the subcutaneous lift was a little easier for me to perform, and because the facial nerve branches were less vulnerable, the subcutaneous lift was also potentially a little safer (even though I never had a facial nerve injury using the deep plane method). And because the subcutaneous flap was not attached to the mandibular periosteum the way the SMAS-platysma layer usually is, it was often easier for me to smooth out the tissues along the jawline when performing the subcutaneous lift.

Furthermore, once I had adopted two simple technical maneuvers, the subcutaneous lift became nearly as “dry” as a deep plane lift, with a very low incidence of post-operative hematoma. With these considerations in mind, a few years ago I switched to the subcutaneous lift as my primary method of cheek-lifting.

One of the two simple hemostatic tactics I incorporated into the subcutaneous lift was to use electrocautery for a good deal of the flap dissection. The other tactic was aimed at avoiding the *late rebound bleeding* that is encountered when the local anesthetic solution contains epinephrine in the usual dilution of 1:200,000 to 1:400,000, which at times leads to the development of recurrent bleeding and possible expanding hematoma formation *after* the skin incisions have been closed. For that reason, for several years I completely eliminated the use of epinephrine (as advocated by Drs. Barry Jones and Rajiv Grover), which I found beneficial. Recently, however, I have begun to use epinephrine again, but now in a very dilute concentration of 1:4,000,000 (1 to 4 million), which seems to provide just enough vasoconstriction for an acceptably bloodless flap dissection, along with a short enough duration of vasoconstriction to allow secure hemostasis *before* the skin incisions have been closed.

When performing a subcutaneous cheek lift, occasionally I will imbricate the subcutaneous fat or the platysma-SMAS layer to fill in a volume-deficient area, such as a hollow submalar zone, or to improve the neck and jawline when I perform a cheek lift without a neck lift, as Little does routinely. However, in most cases, I do no plication of the subcutaneous fat or SMAS in the cheek. I have found that sutures that gather tissue together under the skin of the cheek can at times produce visible bumps and irregularities, distort the corner of the mouth, or create an asymmetry between the two sides of the face. At a recent symposium, Little and Baker, who both do no sub-SMAS flap dissection in the cheek, concurred that a subcutaneous fat or SMAS plication may produce a better-looking and longer-lasting result in many patients and that the disappointing track record of subcutaneous plication observed by Aufrecht, Tipton, and others many years ago could be attributed to the use of sutures that were too few in number, or too small in diameter, or were put in the wrong place. That said, perhaps I will do more subcutaneous plication in the future.

Adjuncts to the Cheek Lift: The Subgaleal Lower Eyelid Lift and the Subgaleal Temporal Lift

When the cheek is lifted upward and backward, excess skin often piles up in the lower eyelid and pretemporal areas. To blend the lifted cheek smoothly with the tissues in the periorbital area, and to prevent the so-called *lateral sweep* that Hamra described, I often perform an auxiliary lower eyelid lift and temporal lift.

This patient is an example of a cheek lift that was done with a complementary temporal lift and a lower eyelid lift. The temporal lift, in addition to preventing pretemporal skin bunching, nudged up the tail of the eyebrow and corrected the small amount of lateral upper eyelid hooding that the patient had. The lower eyelid lift consisted of nothing more than a simple skin excision superficial to the orbicularis oculi muscle and a transconjunctival removal of the excess lower eyelid fat. Because nothing in the eyelid was actually lifted, the apparent elevation of the lid-cheek junction (seen on oblique and lateral views) might better be termed a *virtual lift*.

I have come to appreciate that almost anything that I do that smoothes out the surface or the contours of the lower eyelid will make it appear as if the eyelid had been vertically shortened—whether through removal of excess eyelid skin alone, or a simple redraping of the eyelid skin without removing any skin, or a transconjunctival removal of excess fat alone, or a transconjunctival fat transposition alone to simultaneously improve puffiness and tear troughs, or some combination of those things. This observation is an important one, because for years now, many plastic surgeons have said that to elevate the lid-cheek junction, the surgeon must vertically lift the malar soft tissues as part of a SMAS face lift or as part of a transblepharoplasty mid-cheek lift, and I do not think that is necessarily true.

That said, there are many patients in whom I do a real vertical lifting of the lower eyelid by actually shortening and tightening the lateral orbicularis oculi muscle using a *muscle hitch* stitch or two. At times, I also tighten the lid margin horizontally with a *double-loop muscle-tuck canthopexy*. I will illustrate both of those maneuvers in the section on operative technique (p. 1118). But whether the eyelid lift is a real or virtual one, it is often an important component of a truly successful rejuvenation of the face.

As for the temporal lift, whose purpose is simply to lift the pretemporal skin and the skin at the tail of the brow and lateral orbital area, the question that is frequently asked is: why do it, as I do, by way of a subgaleal dissection, when a subcutaneous dissection would be more direct and more efficient? My answer has five parts. First, if the scalp incision were to be placed behind the hairline and a subcutaneous dissection were to be done, there is a small but real risk of alopecia. Second, I prefer to avoid a skin incision along the temporal or frontal hairline, where it may leave a visible scar. Third, excising hair-bearing scalp behind the hairline (which I rarely do with my temporal subgaleal lift) can noticeably elevate the hairline. Fourth, the subcutaneous plane in the forehead may not be an easy plane of dissection, and it is always well-vascularized. Obtaining a satisfactory hemostasis can take a good bit of time, and should a hematoma develop under a thin forehead skin flap, there is some risk to the flap's blood supply. Fifth, the sensory nerves in the lateral forehead lie on the surface of the frontalis muscle, and they can be easily injured during a subcutaneous dissection.

The subgaleal temporal lift that I do is quick and easy. It is performed under direct vision without the endoscope and takes about 15 minutes on each side. Alopecia, numbness, flap viability, and incision scar visibility are of little concern, and because I rarely remove skin, the position of the hairline is minimally altered.

Preoperative Evaluation and Indications

Making the case for a cheek lift is an interaction of subjective patient aspirations and objective physical findings that is done on a case-by-case basis. From my point of view, there are nine indications—each alone may be reason enough for a lift, but they often appear, naturally, in some combination: a bothersome nasolabial fold; an unattractive labiomandibular fold; wrinkled, sagging cheek skin; inferior displacement of the soft tissues from over the malar eminence; an age-related submalar hollow; increased visibility of the lateral infraorbital rim; a cluttered appearance to the jawline; a pronounced jowl; and a chubby lower cheek. Of course, the cheek lift may be combined with a neck lift, a temporal lift, a small-incision brow lift, a blepharoplasty, or some other ancillary procedure.

Patient Profiles

This 48-year-old woman was bothered by mild nasolabial folds and short labio-mandibular folds. When I lifted her cheeks with my hands during the preoperative examination to simulate the effects of a cheek lift, something I always do, those early signs of medial cheek relaxation were completely eliminated without producing an associated bunching up of the skin in the lower eyelid or pretemporal area. Her neck needed no intervention. Together we decided on isolated small incision cheek lifts and upper blepharoplasties.

Preoperative

1 week postoperatively

Preoperative

1 year postoperatively

This 64-year-old patient was quite certain that she wanted a cheek lift without a neck lift because of the perceived complexity of the combined procedure. However, her lower eyelids were puffy and tired looking, so she acquiesced to having them rejuvenated at the same time. Because the preoperative simulated cheek lift produced skin bunching in the pretemporal area, I felt that a temporal lift was mandatory, as was an undermining of the skin of the neck just below the earlobe to prevent a vertical skin fold from forming there (see the description of the *pushup maneuver* in the section on the cheek-lift skin incision), both of which the patient also accepted. She understood that the cheek lift would not improve the wrinkle lines in her lips at all. The procedure that was done for her was an isolated subcutaneous cheek lift, along with a temporal lift, and a lower eyelid lift (a transconjunctival fat removal, a vertical *muscle hitch*, and a skin strip excision). The jawline skin was undermined 2 fingerbreadths below the lower mandibular border so the jowl could be trimmed under direct vision. She is shown 1 week (*top right*) and 1 year (*bottom right*) after surgery. All of the improvement in her neck resulted simply from lifting the skin in her cheek.

In the 5 years preceding her consultation, this 52-year-old woman observed a gradual downward drift of the tissues in her brows, eyelids, cheeks, jawline, and neck, which together bestowed a tired appearance. I performed a subcutaneous cheek lift, along with small incision endobrow lifts, upper blepharoplasties with ptosis correction, lower eyelid lifts, and a neck lift. The cheek lift restored a youthful fullness over the malar eminence, which can be seen as a more generous ogee curve (*yellow arrow*) on the postoperative oblique view. Although the cheek was actually lifted obliquely upward toward the upper preauricular fixation point along a vector perpendicular to the nasolabial crease, it seems as if the malar fat pad actually had been lifted vertically upward. The small jowl that was present preoperatively (*white arrow*) was also lifted obliquely upward as part of the cheek flap. However, I have found that if the jowl is any bigger than this small one, the most effective and stable treatment is a surgical trim of the excess jowl fat under direct vision, as was done for the previous patient.

This 58-year-old woman disliked her lower nasolabial folds and labiomandibular folds, her jowls, and the small wattle under her chin, but she was content with the appearance of her upper cheeks and periorbital areas. When I lifted her lower cheeks during the preoperative examination, the lower eyelid and upper cheek did not display a *lateral sweep*. Therefore a *lower cheek lift* was done in conjunction with a neck lift. No temporal lift and no lower eyelid skin excision were necessary—only a transconjunctival removal of some excess lower lid fat. A lower cheek lift is done using the same incision as that used for a full cheek lift, except that a bit less undermining is done across the upper malar zone and lid-cheek junction over toward the side of the nose than I usually do for a full cheek lift.

In some patients, recontouring the subcutaneous tissues is the component of the cheek lift that is most responsible for rejuvenating the face. In this patient, a carefully tapered excision of excess lower cheek and jowl fat was done under direct vision, which transformed the patient's lower face from a square shape to a more attractive and youthful-appearing oval.

At the preoperative consultation, patients often ask, "How long will the lift last?" I tell them, "The most unpredictable part of any face lift is the durability of the flattening of the nasolabial fold or the labiomandibular." In my practice, the average time is 8 years—but it can be as short as 2 to 3, or as long as 10 to 15. That's because there are three factors at play, and I can influence only one of them—which is how the surgery is done. The other two factors are genetically determined and out of our control: how easily the skin stretches back after it has been tightened, and

how well the scar bond that glues everything back together holds up. In some people that bond is tight and does not allow the tissues to slide downward again easily. But in other people, that scar is thin and slippery. So I turn the clock back, but then it starts to tick again, and how long it takes to get back to where we started is anyone's guess. That said, you'll still always look better and younger having had the lift than if you had not. For example, I may make you look 50 instead of 60, so when you're 70, perhaps you'll look 60; when you're 90 maybe you'll look 80. But I do not freeze you at 50." Most patients then say, "Okay, I get it."

One last comment regarding the indications for various methods of cheek-lifting. If the patient is a smoker or has diabetes or some other kind of microangiopathy, or if there are scars on the patient's cheek that might interfere with the blood supply to the flap, then at the least I would perform a less-extensive undermining of the cheek flap and anchor the flap under less tension than I usually do. Or I might play it even safer, and elect to do a deep plane lift.

Sequencing the Procedures

I find it convenient to perform the temporal lift or endobrow lift first, before the cheek lift. If a procedure is to be done on eyelids, I first complete the cheek lift and neck lift to minimize the bruising around the eyes. A light dressing and/or cold compresses are applied to the periorbital area immediately after the surgery is completed.

Planning

The Cheek-Lift Skin Incision

With rare exception, I use the same skin incision in every female and male patient. At the level of the lateral canthus, the marked incision runs barely above the lower edge of a short sideburn, or through a longer sideburn, in a lazy-S fashion that fol-

lows the natural sinuous curve of the hairline. I always place the lateral centimeter of the incision along the very top edge of the little hairless triangle that separates the sideburn from the front of the upper ear—not a little farther down, where some surgeons place it, because that little bit lower can make the scar visible if the hair there is pulled up. Placing the incision no higher than the lower edge of the sideburn rather than running it up into the temporal scalp prevents the sideburn and the hairless triangle from being shifted upward, which is an unnecessary and often undesirable result. With the design described, the cheek lift can be repeated any number of times with the sideburn and its hairline remaining in their original position.

Incorrect

Correct

It is best generally to avoid using the word “never” when talking about aesthetic surgery. However, in regard to cheek-lift incisions, there are some things I never do. In a first-time cheek lift in a woman, I never draw and cut the incision as a straight line, as seen here (*left*), which has produced a sawed-off, unnatural appearance. A straight incision can be acceptable in a male patient, either because the scar is hidden within an endless sideburn and would not determine its final shape, or because most men shave their cheeks in a way that purposely leaves a straight rather than curvy edge. In a female patient, a high, flat border seems artificial, and since it is just as easy to leave the patient with a nice U-shaped sideburn, as suggested in the photo (*right*), why not do that?

I also never put a new incision at the front of the sideburn—not even a little—unless there is one there already. One or 2 years after surgery, a mature scar along the front of the sideburn often will have turned white in color, making the scar visible and possibly bothersome to the patient, as it was for the two patients seen here. Because the direction of hair growth in the sideburn is backward, the hair there cannot naturally conceal a pale scar. I find that cutting a zigzag incision edge and placing it a bit behind the hairline for camouflage is not particularly helpful. And while other maneuvers, such as beveling the incision and foregoing the electrocautery to protect the hair follicles and melanocytes, thinning the trimmed edge of the overlying skin flap to allow the hair to more easily grow through the scar, and avoiding tension on the closure, do produce inconspicuous scars in some cases, those maneuvers are not always successful. For that reason I think it is best to avoid a scar at the front of the sideburn in every case, since there are other technical maneuvers that can be used that entirely obviate the need for an incision there.

I avoid a scar at the front of the sideburn by doing two things. First, I rely on the temporal lift to clear away any excess skin that the cheek lift may deposit in front of the sideburn (*left*). Second, I compromise just a little on the amount of vertical lift

I apply to the cheek flap by adjusting the flap's swing around its pivot point at the anterior end of the incision at the lower edge of the sideburn (*white X in the photo, right*). This sometimes shifts the flap's dog-ear from the front of the sideburn to the base of the earlobe, but I would rather chase the dog-ear behind the ear, where a short scar in the sulcus will be completely hidden, than chase the dog-ear to the front of the sideburn, where the scar might be visible.

The incision may end at the anterior base of the earlobe or in the postauricular sulcus.

Below the sideburn, the incision continues downward, tightly hugging the front edge of the upper ear. Then it dips just behind the crest of the tragus (not on the crest) where it will not be seen. Even when I am doing a secondary or tertiary cheek lift, I almost always try to end up with a retrotragal incision scar. Usually I can create a small superiorly based transposition flap from the excess skin in front of the earlobe to swing over the tragus in reoperative cases. Pretragal scars may at times be hard to see, but they may also be noticeable—it's a roll of the dice. If a nice pretragal depression is created, and if the tragal flap is cut to fit, properly thinned, and set in place under absolutely no tension, a retrotragal scar is a much better choice than a pretragal scar in almost every case. Once in a while I will see a male patient for a secondary face lift who had a pretragal incision positioned along the posterior edge of his whisker line in front of the ear—something I personally would not do. But if that scar happened to heal imperceptibly, with an excellent color match, I probably would use that same incision again for the patient's secondary procedure to preserve the glabrous strip in front of the ear, but that is an unusual situation.

At the lower apex of the tragus the incision jogs out at a right angle for a few millimeters to create a definite visual endpoint to the tragus (an important detail described by Bruce Connell), and then the incision nestles into the crease at the top end of the earlobe. If I am performing an isolated cheek lift (that is, a cheek lift without a neck lift), the incision ends either at the anterior base of the earlobe or behind the earlobe in the lower postauricular sulcus.

Preoperative Pushup Maneuver

I can determine exactly where the isolated cheek-lift incision needs to end behind the ear using a simple preoperative test that I call the *pushup maneuver*. I put a finger on the lower cheek just above the angle of the jaw and push upward, simulating the effect of the cheek lift on the skin around the ear. Usually that pushup produces a vertical skin fold below the earlobe (*white arrow*). I draw a circle on the skin around that fold, which indicates the additional area of skin that I will need to undermine in continuity with the undermined cheek flap to redistribute the skin there (*center*). That will prevent a skin fold from forming below the ear when the cheek is actually lifted. It is obvious then to see how far up behind the ear the skin incision will need to run to easily and adequately release and redrape the skin within the outlined circular area.

Sometimes the preoperative pushup maneuver produces no skin fold below the earlobe, usually in a younger patient who has relatively snug cheek and neck skin to begin with, or in a secondary cheek lift case. In that situation, the cheek-lift incision can end at the anterior base of the earlobe without extending around behind the ear, which makes for a real *short-scar cheek lift*.

OPERATIVE TECHNIQUE

Temporal Lift Incision

The temporal lift incision is 3.5 to 4 cm long and is placed 2 to 3 cm behind the temporal hairline, with the central point located 5 cm from the superior otobasion, which places the medial end of the incision just lateral to the line of fusion and the path of the deep branch of the supraorbital nerve. The hair is parted but not shaved.

Subgaleal Dissection

The area of the subgaleal dissection is highlighted above in white. To adequately release the tail of the brow for lifting, the dissection must break through the galeal attachments to the periosteum along the lateral orbital rim to enter the retroorbicularis oculi fat (ROOF) of the upper eyelid below the rim. The dense *orbital ligament* at the junction of the superior and lateral orbital rims should also be divided. The frontal branches of the facial nerve run within the galeal fat pad that hangs down from the ceiling of the dissection pocket. Therefore the lower portion of the pocket dissection should be done under direct vision, with the dissecting scissors staying

right on the surface of the white temporal muscle fascia and lateral forehead periosteum. The surgeon should appreciate that once the so-called sentinel vein has been reached, the scissors are close to, but also beyond, the facial nerve branches.

The local anesthetic solution I use for the face and neck is 0.25% lidocaine with epinephrine 1:4 million. The anesthetic I use everywhere in the forehead is 0.25% lidocaine with epinephrine 1:4,000,000 (1 to 4 million). I inject the solution into the subgaleal plane of the area to be dissected as well as into the skin and subcutaneous fat along the incision line and directly down to the periosteum along the lateral half of the supraorbital rim and the lateral orbital rim. The incision is made with the scalpel and then deepened down through the subcutaneous tissue and galea with microneedle tip electrocautery.

I undermine a few centimeters behind the incision (*left*) so the scalp can shift upward slightly to accommodate the lifted flap when it is hiked up, thereby avoiding a transverse hump, because I will be removing no scalp skin with this procedure. I then start the dissection downward (*right*) just on top of the temporal muscle fascia, using the little blunt-tipped iris scissors to push and cut through the wispy *innominate fascia* that lies between the galea and the white fascia covering the muscle.

The little iris scissors are pushing and cutting through the line of fusion onto the lateral forehead periosteum. The extent of blind undermining is shown (*right*) about halfway down toward the supraorbital rim, but no farther, to avoid possible injury to the frontal nerve branches. Farther caudally, I dissect under direct vision until I reach the orbital rim.

With the back of the operating table tilted up, a long, narrow Deaver retractor inserted, and a xenon headlight for illumination, I gently spread horizontally and vertically with the long Metzenbaum scissors directly on the surface of the temporal muscle fascia, keeping the galeal fat pad above the tips of the scissors.

I also watch for the sentinel vein (*left*) so that I do not inadvertently cause it to bleed. It is usually seen 1 cm above the upper lateral corner of the orbital rim. In most cases I preserve the vein and work around it, but if it gets in the way, I cauterize and divide it. Farther medially in the pocket (*right*), I cut through the line of fusion, which I progressively divide as I extend the pocket downward over the lateral forehead to the bony rim.

When I reach a point just above the supraorbital rim, I proceed with the dissection, looking down at the patient from outside the pocket. I spread the scissors open horizontally to tear through the galeal attachments to the periosteum along the lateral half of the supraorbital rim to enter the ROOF of the upper eyelid (*left*). Then I look into the pocket (*right*) to confirm the break-through. The long cautery tip indicates the location of the orbital ligament, which needs to be divided if the tail of the brow is to be lifted.

Sometimes I use the long cautery device under direct vision to open through the galea–periosteal adhesion and the orbital ligament with the aid of a thin suction cannula to aspirate the smoke so I can easily visualize the inside of the pocket. More often, I simply spread and cut blindly with the scissors over to the outside corner of the orbital rim and then around the corner (*right*) to be certain that any attachments there that could inhibit the lift have been adequately released. However, if the intention of the temporal lift is just to prevent lateral orbital and pretemporal skin bunching produced by a cheek lift while maintaining the position of the tail of the brow where it is, then of course, I do little if any dissection at the lateral orbital rim.

I always insert a suction drain. Then I grab the galea and a little fat securely with a small Kocher clamp, evert the flap over my fingertip, and take a nice deep bite of galea and subcutaneous tissue with a 2-0 PDS suture on a taper SH needle in the midportion of the flap about 2 cm from the edge. I find that it is easiest for me to put this stitch in backhand. Then I pass the suture a second time so that I have a generous double-loop bite of tissue that will not tear out when the suture is tied up under tension.

Next I take a big transverse bite of the temporal muscle fascia cephalad to the double-loop bite in the flap; then I tie this horizontal mattress suture up very tightly. To do this I grasp the short end of the first throw of the knot with a small needle holder and pull it straight upward toward the top of the head, while applying countertraction straight downward at the knot with the tip of my other thumb. When that first throw has been cinched up as snug as I can make it, my assistant grabs the knot with the tips of a smooth needle holder so it will not slip before I add the nonslip second square throw. Three more square throws follow. I have found that in most patients it is hard to overdo this temporal lift, because there is always a little downward settling of the tail of the brow as time goes on.

I put in one or two more simple nonmattress sutures laterally between the galea and temporal muscle fascia to increase holding power. For the closure (*right*), the cut edges of the galea are approximated with a running 3-0 Vicryl suture that is hemostatic and prevents scar widening, then the skin is closed with a running 4-0 plain catgut intradermal suture. The suction drain is usually removed after 24 hours. I have found that use of a drain significantly reduces periorbital ecchymosis.

Cheek Lift

Anesthesia and Markings

Next I move on to the cheek lift itself. I inject a solution of 0.25% lidocaine with epinephrine 1:4,000,000 (1 to 4 million) along the incision lines and into the subcutaneous tissues of the cheek. Of course, I also inject the subcutaneous tissues of the neck if I am going to be working on the neck. I then draw two vertical lines on the cheek, the first line 2 to 3 cm in front of the ear and the other line dropped down from the lateral orbital rim to the jawline. I use the cautery to elevate the flap out to the first line, then dissect with small scissors out to or somewhat beyond the second line. Beyond that, I use a combination of cautery and scissors dissection into the far medial cheek.

Flap Elevation

After lightly scoring the incision lines with the scalpel, I use the microneedle tip electrocautery on coagulating current to elevate the flap out to the first blue line without bleeding in the subcutaneous plane superficial to the SMAS; in the process the tragal cartilage is skeletonized and a pretragal depression is created.

In the zone between the two vertical lines, where the skin is held down rather tightly by the lateral and central cheek-retaining ligaments, I use the little curved, blunt-tipped iris scissors (*left*) to first cut a little into the superficial subcutaneous fat under direct vision, then I perform the rest of the dissection using the *blind push-cut technique* (*right*), seeing the tips of the scissors through the skin, which keeps me from dissecting too deeply or too superficially. I have used this push-cut method of flap dissection for 35 years and find it to be the safest, easiest, and quickest way to elevate the flap.

It takes only a few minutes with the Yankauer suction and the long needle-tip cautery to obtain good hemostasis.

Next I undermine down to or somewhat below the jawline with the cautery, taking care to stay superficial to the SMAS-platysma layer. Then I extend the pocket superiorly with the cautery, staying just superficial to the orbicularis oculi muscle, which brings me well up into the territory of the lower eyelid.

The overlay map (*left*) shows what has been done so far with the cautery and with the scissors. Then I use either short iris scissors or long Metzenbaum scissors to blindly make a series of tunnels just under the skin into the medial cheek (*right*), which again keeps me from dissecting too deeply or too superficially.

These tunnels extend almost to the side of the nose, nasolabial crease, corner of the mouth, and side of the chin.

Trimming Jowl Fat

If there is jowl to be trimmed, I undermine the skin for about 2 fingerbreadths below the jawline with the scissors, leaving a 2 to 3 mm cushion of fat on the underside of the skin; then the excess jowl fat can be removed with the cautery after the medial cheek dissection has been completed.

Isolated cheek lift

To complete the medial dissection of the flap, I connect the scissors-made tunnels with the cautery while looking inside the pocket and controlling whatever bleeding was instigated by the scissors dissection. The overlay dissection map above shows how the completed dissection is usually accomplished with cautery and scissors for an isolated cheek lift. Occasionally, however, if the subcutaneous fat in the medial cheek is soft and opens up easily and safely with cautery, I may do most, if not all, of the medial cheek dissection with electrocautery alone. At other times, I may do almost all of the medial cheek dissection with scissors, using the push-cut technique without first making disconnected tunnels.

Combined cheek-neck lift

When I perform a cheek lift with a neck lift, I usually wait to do the medial cheek dissection until after I have elevated the neck flap and joined the subcutaneous pocket in the neck with the subcutaneous pocket in the lateral two thirds of the cheek across the jawline. Once that has been done, the cheek flap tents up much more easily (*right*), allowing me to quickly and safely dissect all of the medial cheek using just the cautery, with no scissors. Thus there is no bleeding at all, even when the fat of the medial cheek contains a lot of fibrous tissue and is quite vascular.

This overlay map summarizes the dissection done with the cautery and scissors for a combined cheek-neck lift.

Flap Fixation and Incision Closure

My final assessment for hemostasis is done with the patient's blood pressure at or above his or her preoperative systolic baseline. If it is below that level as I near the end of the operation, titrated amounts of ephedrine are given intravenously until the patient's normal or supranormal level has been reached.

Regardless of how dry the wound may seem after that last look, I always leave a suction drain in each cheek. If I am performing an isolated cheek lift without a neck lift that does not require skin undermining below the earlobe or below the jawline, the TLS drain (size 10 Fr) that I use exits through the lower temporal scalp above the front of the ear and lies obliquely under the cheek flap with its end close to the corner of the mouth. If I do undermine the skin below or behind the ear or below the jawline with an isolated cheek lift, I place a second drain into the small infraauricular pocket that exits through the skin of the upper postauricular sulcus behind the ear. I've found that using one long drain that curls upward above the jawline to also drain the cheek area, placed into the small pocket below the ear, does not work very well. If either area should develop a collection of blood or a hematoma, resulting in occlusion of the single drain, the other area would also be deprived of drainage. Two separate drains are always better than one. When I perform a combined cheek and neck lift, I always use one drain for the cheek and another separate drain for the neck on each side. Cheek-lift drains are often removed 24 hours after surgery. Neck-lift drains, on the other hand, usually need at least 48 hours before removal.

I have listed here the objectives and considerations that I have in regard to the fixation of the cheek flap. Put simply—I want it tight, but not too tight:

- Capture the benefit of the extensive flap undermining.
- Counteract elastic skin stretch-back and flap slippage.
- Hold the lift until solid healing has taken place.
- Place tension on the flap, but none on the skin closure.
- Avoid compromising the blood supply of the flap.

For the flap fixation, a 2-0 PDS suture on an SH taper needle is used. As shown (*left*), I take a deep bite where the blue line has been drawn, which should catch something solid, so that when I lift up on the suture (*right*), the ear does not move and I can tell that I am into periosteum and not just deep fascia.

The cheek flap is grasped with both hands, thumbs under the flap, index fingers on top. I pull the flap firmly backward and upward in a direction that makes the jawline and medial cheek tissues look their best, and I mark the place where the flap touches the fixation point with the tip of my left index finger. Then I turn the flap over, and at the tip of my index finger I take a small but solid bite of fat, along with a little deep dermis. I have found that I do not need a big bite of tissue here to keep the suture from tearing out when it is tied under tension.

An economical bite of tissue is taken into the lining of the flap (*arrow*). Because I make both passes of the suture needle in a forehead direction—one pass into periosteum at the fixation point, and the other into the flap—this suture is really a figure-of-eight stitch. I tie that suture so that the flap is pulled up quite snug, but I never cinch the knot down all the way. As can be seen (*right*), I purposely leave some space under the knot to prevent strangulation of the small blood vessels in the surrounding skin and to retain some play for final positioning of the flap, which I will want when I close the skin incision to avoid a dog-ear in front of the sideburn. In both photos above, notice that the cheek drain was placed under the flap before the fixation suture was inserted.

The needle holder has been placed beneath the tied suture loop (*left*). This one fixation suture functions as a very *short leash*—it does all the work of holding up the flap. I always release the tissue a little just under the skin edge in front of the upper ear with the cautery (*right*) to ensure that the ear has not been pulled forward at all by the anchoring stitch.

The skin incisions have already been closed, as shown, but before that, I examined the flap to see whether a skin dimple had been created by the fixation suture. A shallow dimple, like the one seen here (*arrow*), will not compromise the blood supply to the flap and will disappear in a few months as the fixation suture dissolves. If there had been a deep dimple or a blanched line in the skin radiating downward from the dimple, I would have known that I had either tied the suture too tightly, or taken too deep a bite of tissue on the underside of the flap. A deep dimple will often result in some superficial skin necrosis in its depth, leading to crusting and a little scarring, while a blanched line in the skin may well portend more extensive tissue loss. That being the case, if I see a deep dimple or a blanched line, I cut out the suture and insert a replacement, taking a bite in the flap that grabs less fat and dermis, then I tie the suture down less tightly, leaving a bigger loop below the knot. I have learned that a little less tension on the flap can avoid problems and will not noticeably diminish the quality of the result. Because this is a skin flap, not a thicker composite flap or SMAS flap that is hidden from sight, it cannot be safely tied up as tightly.

Before beginning the closure, I inject all of the exposed skin edges and the subcutaneous tissue on the underside of the flap a few centimeters in from of the flap edge with the lidocaine-epinephrine solution so there will be very little bleeding when I cut and trim the flap.

A small Kocher clamp grasps the top point of the flap and a second clamp grasps the upper crest of the small flap that once covered the tragus. The two clamps are fanned out and the flap rotated upward as much as possible without creating a dog-ear—not even a small one—at the front of the sideburn. A dot is made on the skin at the cephaladmost point of the preauricular incision (*arrow, left*), and the flap is cut down to that point. A curved line is then drawn on the skin (or in the surgeon's mind) that mimics the undulating lower edge of the sideburn, and the excess flap overlying the sideburn is trimmed along that line. The electrocautery is used to seal new bleeding vessels along the cut edge.

A 4-0 Prolene tacking skin suture has already been placed at the superior otobasion (*left*), and the excess flap overlying the earlobe is being carefully cut over to the lower apex of the tragus at the front of the ear so that there will be enough flap skin rotated upward to cover the tragus, while also leaving some excess flap at the base of the earlobe to allow a perfectly tailored inset.

Two or three small crescents of skin are carefully and incrementally carved from the flap just below and just in front of the earlobe (*left*) to allow the earlobe to sit comfortably in its normal position with the raw skin edge at its base abutting the raw skin edge of the just trimmed cheek flap without the help of any sutures. Nonetheless, I usually insert a stabilizing 5-0 PDS subcuticular suture there (not shown in the photos). Then the excess skin flap overlying the front of the ear is splayed out and pulled gently backward with the two small Kocher clamps, and while peering under the flap, I make a dot on the skin at the upper apex of the tragus, then cut the flap carefully down to that point, making small course corrections as I go. I do not want to overcut past the notch at the upper end of the tragus, because I do not want to create any tension at all on the skin closure at the front of the tragus.

The skin flap that will cover the tragus is then turned back and thinned by excising most of the underlying fat almost down to the dermis.

Small bleeding vessels under the thinned flap are judiciously controlled with the cautery, and a 5-0 nylon skin suture is placed above and below the tragus. I never use a buried suture at the front of the tragus to hold the flap into the pretragal depression; that suture could easily jeopardize the blood supply to the little flap and is entirely unnecessary. The flap will settle and stick down nicely on its own into the excavated hollow I made for it there. A small, curved skin flap is then designed and cut to drape over the tragus without tension. After I remove the excess skin there, I grasp any fat poking out from under the back edge of the tragal flap with a small forceps, and as I gently pull the fat out from under the flap, I trim it off with the small iris scissors while lightly pressing the blades of the scissors up against the undersurface of the flap. This thins the little flap safely just a bit more. Then the remaining excess skin flap draped over the front of the upper ear is trimmed away.

The entire periauricular incision line is then closed with a single running 4-0 plain catgut intradermal suture with the knots tied outside. If these catgut knots have not fallen away on their own by the first postoperative office visit 1 week after surgery, I snip them off at that time and remove the 5-0 nylon skin suture above and below the tragus and the 4-0 Prolene suture at the top front of the ear.

Lower Eyelid Lift

Now that the cheek lift has been completed, and perhaps a neck lift as well, I want to illustrate the lower eyelid lift that I so often do with the cheek lift. I have used intraoperative photos of several different patients for this sequence to ensure that each step is clearly demonstrated. However, I am not going to describe here how I manage excess lower eyelid fat, except to say that it is usually done by a transconjunctival removal; nor how I treat a bothersome *tear trough* at the lid-cheek junction, except to say that it is usually managed with a transconjunctival fat transposition. As a general rule, if I work on the eyelid fat, I approach it through the conjunctiva, and if I work on the eyelid skin or the orbicularis oculi muscle, I do that without cutting into the orbicularis oculi, not because I think that denervates the pretarsal muscle (I do not think that it does), but because empirically I have experienced a lower incidence of postoperative lid retraction problems if the integrity of the muscle is strictly maintained.

Estimating Amount of Lower Lid Skin Excision

I like to estimate preoperatively the amount of skin that I am likely to excise. Lifting the lower eyelid skin with my fingers creates a skin fold just under the eyelash margin, indicating the required length of the subciliary incision. I then draw out that subciliary incision line, along with a short lateral limb that extends beyond the lateral canthus in one of the crow's-feet lines. The lateral eyelid skin is again pinched and lifted, and the excess skin is rolled under. Where the upper edge of the rolled-under skin touches the lateral canthal point, I make a dot with the marking pen (*black dot at the arrow*). Then the medial and lateral ends of the subciliary incision are connected with a gently curved second lower line that runs through the lower black dot.

Anesthesia and Incision

I use a solution of 1% lidocaine with epinephrine 1:100,000 for local anesthesia when performing a blepharoplasty. All eyelid procedures are performed with corneal shields temporarily in place. The lateral segment of the skin incision is lightly scored with the scalpel and the subciliary segment cut with small sharply pointed scissors superficial to the underlying orbicularis oculi muscle. A suture is placed laterally along the lid margin for countertraction, and the separation of the muscle from the skin is begun—at first under direct vision (*right*), and then by seeing the tips of the scissors through the eyelid skin—which is a good way to dissect quickly under the thin skin without creating a buttonhole.

Dissection

I always dissect beyond the blue estimation line, freeing up the skin as far caudally as needed to eliminate all of the skin wrinkling. If there is a malar festoon present, I separate the skin from the muscle down to the upper edge of the festoon.

Hemostasis is obtained with the electrocautery on a low setting.

Lateral Canthopexy

If the patient has a hypotonic lower eyelid, often manifested by a downward rounding of the lateral lid margin or some degree of increased scleral show, I perform a lateral canthopexy—one that I call the *double-loop muscle-tuck canthopexy*—which tightens the pretarsal muscle and the lid margin in a horizontal direction. For this, a permanent 4-0 Prolene suture on a taper SH needle is used. With my assistant's fingers gently pulling the mobile soft tissues at the lateral orbital area upward and outward, I locate the inside edge of the lateral orbital rim with the tips of the forceps.

I then insert the needle into the orbicularis oculi muscle just below the skin of the lateral lower eyelid margin and just medial to the lateral canthus, catching hold of the periosteum on the inner edge of the lateral orbital rim at or just slightly above midpupillary level. The tip of the needle can be seen emerging through the periosteum and muscle laterally (*arrow*). When I pull up on the suture (*right*), it should feel solidly engaged in the periosteum.

I pass the needle a second time exactly the same way, creating a double-loop of the suture. When this suture is tied, the muscle within the double-loop is gathered and tucked up against the bone just inside the lateral orbital rim, where it is meant to heal securely. It is important that the needle pass through the periosteum on the inner edge of the lateral orbital rim both times, not the outer edge, to avoid an “air space” between the lateral lid margin and the globe. It is also important that the suture not pass through the tarsus, which could kink the lateral lid margin when the suture is tied. This is a muscle-tuck canthopexy, not a tarsal-tuck canthopexy.

My first tie is a surgeon's knot, followed by two more square throws. The ends of the suture are cut flush with the knot. Usually the lid margin above the knot is puckered or pulled down a little by having the muscle crimped just below it. It is very important that I correct that distortion, even if it is minor, by snipping just above the knot with the little scissors to set the lid margin back in a perfectly normal position.

Muscle Hitch Procedure

I do a vertical tightening of the lateral orbicularis oculi muscle, a *muscle hitch*, for one of several reasons: if I simply sense that a muscle lift will impart a smoother appearance to the lower eyelid or the lid-cheek junction; if the lower eyelid seems hypotonic—characterized by a lateral rounding of the lid margin or an increase of scleral show; if I want to increase the stability and security of the muscle-tuck canthopexy; or if I want to correct a malar festoon, which is often a combination of skin laxity and muscle laxity.

The muscle hitch is a horizontal mattress suture anchored to the immobile periosteum of the lateral orbital rim. The amount of vertical muscle lift obtained depends on how far below the rim the suture is placed into the muscle. The more the lift that is desired, the farther downward the skin will need to be separated from the muscle. Just a little lift requires just a little undermining of the skin. More lift means more undermining—often 1 to 1.5 cm below the lateral canthal area.

For the muscle hitch, I use an absorbable 4-0 PDS on a taper SH needle. As was done with the canthopexy, the periosteum on the inside edge of the lateral orbital rim is captured with the needle (*arrow* indicates the emerging needle tip). Then a wide transverse bite of muscle is taken almost as far caudally as the skin has been undermined (*right*). This must be a generous and solid bite of muscle that will securely hold in the fragile muscle. When this suture is tied, I can clearly see the entire lower eyelid move upward with it.

Once again, if the skin edge has been pinched down a bit by the muscle hitch, it must be freed by cutting the muscle just a little right under the skin.

I then insert a second hitch stitch, much smaller than the first, to add a bit more lift and security to the muscle fixation. This second mattress suture also smoothes out any irregularities along the upper edge of the muscle that was rolled under by the first hitch. This time, however, the needle grabs hold of the periosteum on the outer edge of the lateral orbital rim (*left*), then picks up a small bite of whatever muscle is still available for lifting just under the cuff of skin (*right*).

And once again, I make sure that the skin edge is not distorted (*left*). With the combination of two muscle hitch sutures, I have usually lifted and secured the muscle just about as much as possible (*right*).

For me, eyelid skin excision or skin redraping is the last step—done as the one and only lower blepharoplasty maneuver, or after a transconjunctival fat removal or fat transposition, or after a muscle hitch and/or canthopexy. If there was just one place in plastic surgery to exercise restraint, excising skin from the lower eyelid would be that place. It is much better to leave a little bit of extra skin behind than to remove a bit too much and risk even a hint of lid margin retraction.

For a smoother and more refreshed appearance, some wrinkled lower eyelids just need to have the skin separated from the underlying muscle and then redraped without removing any skin at all—even when more skin has been brought up into the eyelid with a cheek lift. This is particularly true if the eyelid margin was lifted upward with a muscle hitch and/or a canthopexy.

The freed skin flap of the lower eyelid is laid out without any tenting or tension. If there is some excess to remove, it is conservatively marked and trimmed. In the patient on the left, that amounted to only a tiny triangle; in the patient on the right, it was a good bit more. In most cases, the preoperative estimate will come close to the new mark.

I close the subciliary incision with a 4-0 Prolene intradermal pull-out suture, taking only tiny, wispy bites under the skin. The short medial and lateral tails of the pull-out suture and the lateral crow's-feet extension of the incision are covered with a small piece of 1/4-inch Steri-Strip, and then 1/2-inch Steri-Strips are applied to the skin of the lower eyelid to provide vertical support; in addition, the little bit of pressure that the tapes apply to the skin somehow reduces postoperative bruising and swelling.

After the pull-out suture has been removed 1 week after surgery, with the patient sitting upright, I place the tips of my thumbs under the lower edge of the lateral tarsal plate on the left and right sides and push the lower eyelid margins straight up, somewhat forcefully, to stretch out the eyelid tissues. This simple maneuver corrects any pleating along the eyelid margin that may have been produced by the running intradermal suture, and this allows the lid margin to once again hug the globe.

Postoperative Care

My office operating suite is physically connected to an inpatient hospital, so I keep all cheek-lift patients in the hospital at least 24 hours. If they also had a neck lift, the patients stay for 48 hours, because that is when I usually remove the subcutaneous drains. Occasionally, however, a patient will go home or to a hotel with a drain or two left in and then return to my office a few days later to have the drains removed. When told that leaving a drain in longer than expected means less bruising and less swelling and a quicker recovery, most patients readily except the short period of inconvenience.

If eyelid surgery was part of the face lift, cold compresses to the eyes are used for at least 12 hours after surgery, and beyond that, only when the patient wishes to use them for comfort. I remove the light wrap-around face-neck-forehead gauze dressing the morning after surgery so that I can have a look at things, and also because

most patients are more comfortable without the dressing. At that time I clean all the suture lines so they are crust free, including those along the lower eyelid margins. The morning after surgery, the eyelashes of the upper and lower eyelids are often stuck together, making it difficult for the patient to see. The nurses, understandably, do not do a very good job of separating the glued-together top and bottom lashes, so I do that myself with cotton swabs moistened with peroxide while the patient, at first, keeps the eyes closed. At home, however, patients are told not to use peroxide, but only warm water and perhaps a little Johnson's Baby Shampoo—which will not sting the eyes.

I tell patients that as soon as they get home, and as long as they do not feel dizzy, they can get in the shower and wash their hair using any kind of shampoo and hair conditioner, can also blow-dry their hair, and this can be done as often as they wish. Nothing makes a patient feel better than a clean head, and the soap and water running over the incision lines helps to keep them crust free. Since the incisions are by then nicely sealed, there is no increased risk of infection. I do not routinely have the patients apply an antibiotic ointment to the suture lines: it is a bit messy and usually unnecessary.

Most patients take a prophylactic oral antibiotic for 1 week after surgery. If they have a history of ever having had a cold sore, they also take an antiviral medication for 1 week, such as valacyclovir.

During the week after surgery, a walk around the block, some fresh air, or perhaps a movie can all be good for the patient's spirits. Of course, the usual admonition of "keeping the head above the heart level" is recommended for 1 or 2 weeks, with no strenuous exercise for at least 3 to 4 weeks.

Suture removal is done 1 week after surgery. The next office visit after that is usually at 3 months, but if either the patient or I have any concern about anything, the patient is encouraged to return as often as necessary for treatment or reassurance.

The majority of patients are comfortable returning to work and most of their social activities at 2 to 3 weeks after surgery, but an occasional patient will need longer. Every patient is told that the amount and duration of postoperative swelling and bruising is quite variable.

Complications and Outcomes

The reason I particularly like the technique described in this chapter is that the incidence of associated problems is quite low, while the quality of the results is consistently good to excellent. In other words, the risk-to-benefit ratio is a very favorable one.

The incidence of postoperative hematoma has been kept well under 1% because a good deal of the flap dissection and all of the fat excision is done with the electrocautery; late *rebound bleeding* is avoided for the most part by using a very dilute solution (1:4,000,000) of epinephrine. Maintaining or regaining a normal or supra-normal blood pressure during the final hunt for hemostasis before closure has helped as well. The routine use of closed suction drainage for at least a day or two following surgery has, for the most part, avoided the puddles under the flap that produce swelling and ecchymosis.

To achieve an effective temporal brow lift, the necessary freeing of the soft tissues to the periosteum along the supraorbital and lateral orbital rims has produced a 6% incidence of temporary brow elevator (frontalis muscle) dysfunction, which may take several months after surgery for complete resolution. All patients are apprised of this possibility during the preoperative consultation. I have not had a single case of permanent frontalis muscle dysfunction. There have been no buccal branch, zygomatic branch, or marginal mandibular branch facial nerve injuries, temporary or permanent, associated with the subcutaneous flap technique in my hands.

A visible dimple in the skin in front of the upper ear is a frequent sequela of the skin-to-bone method of skin flap fixation. The dimple is usually a shallow one that in most cases can be camouflaged by the hair. Typically, the dimple disappears in 3 to 4 months as the absorbable fixation suture dissolves.

Because the small, crescent-shaped skin flap that is made to fit over the tragal cartilage has its subcutaneous tissue thinned almost to dermis, there have been some instances of superficial skin loss along the edge of this little flap. An optimistic expectation of outcome transferred to the patient, along with a dab of antibiotic ointment and a little time, is all that is usually needed for the scar there to become unnoticeable.

Results

For this 60-year-old woman, I did a subcutaneous cheek-neck lift and temporal lifts. An extensive undermining of the cheek flap was done with a point-tensioned fixation of the flap. The jowls were trimmed under direct vision. Her more youthful-looking complexion resulted from the skin lift alone. The postoperative photos were taken 1 year after surgery, as were the postoperative photos in the other patient examples to follow. I operated on this patient many years ago, before I had come to appreciate the value of a concomitant lower eyelid lift in improving the quality of many cheek lifts. In this case, flattening, smoothing, and lifting the lower eyelids with an apparent elevation of the lid-cheek junction would have further improved her nice result.

This 48-year-old woman underwent a combined cheek and neck lift, along with temporal brow lifts, a narrow skin strip excision from just the right lower eyelid, skin redraping without skin excision in the left lower eyelid, and dermabrasion of the upper lip. The patient reported that even as a young woman she had full upper nasolabial folds, and despite my having undermined beyond the folds over to the lower sidewall of the nose and onto the lateral upper lip to release the *intrafold filaments* that are often primarily responsible for maintaining the humped shape of the folds, the shape of these particular folds persisted, because they were simply a mound of localized fat that had always been there. Had the patient said to me at the preoperative consultation that she would like to have her upper nasolabial folds diminished, I would have done a closed liposuction there at the beginning of surgery before the cheek flaps were elevated.

Aside from her full, firm, oblique neck, this 57-year-old woman was bothered mostly by her chubby lower cheeks and prominent jowls. She had a subcutaneous cheek and neck lift that included lower cheek subcutaneous lipectomies, buccal fat pad excisions, and a jawline clean-up. For the neck, an extensive subcutaneous fat removal was done, along with a subplatysmal fat excision, a perihyoid fascia release, a low release of the anterior digastric muscles, partial resection of the right anterior digastric muscle, partial resection of enlarged submandibular salivary glands, a corset platysmaplasty, and correction of pixie earlobes. Temporal brow lifts prevented soft tissue from bunching in the lateral orbital areas when the cheeks were lifted and also corrected the slight ptosis of her lateral brows. Transconjunctival removal of excess lower eyelid fat was done, and skin strips were excised from both the lower and upper eyelids. As with the previous patient presented, this woman also had unyielding upper nasolabial folds caused by excess fat. In both cases, those folds could have been reduced by narrow-cannula closed liposuction.

At her consultation with me, this 63-year-old woman reported that 4 years earlier she had had lower blepharoplasties and a perioral dermabrasion done elsewhere. She was now discontented with the persistent puffiness in her lower eyelids, the development of jowls, vertical webbing at the front of her neck, and soft tissue relaxation in the lower cheeks—especially the labiomandibular folds.

I performed a subcutaneous cheek-neck lift, jowl fat excision, temporal brow lifts, bilateral transconjunctival fat excisions, and a unilateral right lower eyelid double-loop muscle-tuck canthopexy to lift and tighten that one eyelid margin a bit. Today I would have added a muscle hitch or two on top of that. I had thought that I would also excise a very narrow skin strip from the lower eyelids as well, but at surgery I found that both lower lids needed all of the existing skin, so the eyelid skin flap on each side was simply elevated and then redraped.

This 54-year-old woman came to me still looking younger than her age—but a subtle and yet discernible downward displacement of the soft tissues of her face had begun to tell its tale. The fullness that once enriched her malar eminences had diminished. Some portion of the mid cheeks had settled near the jawlines, leaving a shadowed submalar hollow. Even the lower eyelids had lost a measure of tonicity, where a trace of lateral rounding had become evident. Prominent glabellar frown lines imparted an angry expression, particularly since they were paired with her actively arched lateral brows—an expression that was not at all softened by a pursed-looking upper lip with a stingy vermillion.

I performed a subcutaneous cheek-neck lift, along with low temporal lifts to prevent skin bunching in the pretemporal regions, but done in a way that entirely avoided lifting the lateral eyebrows—not even one millimeter. In the neck, a slim strip of upper midline interplatysmal fat was excised to make room for the joined platysma edges rolled inward with a corset platysmaplasty. The excess neck skin was widely undermined, allowing it to shrink and slide to the sides without the need for any neck skin excision.

For her thin and somewhat puckered upper lip, a direct vermilion lift was done to create a more generous red lip topped by a much prettier cupid's bow. She is seen (*right*) 1 week after surgery.

In the lower eyelids, vertical tightening muscle hitches were used, along with the excision of a narrow bit of skin. Her glabellar frown lines were improved by transpalpebral corrugator muscle resections. En route to the corrugators, a little excess fat in the medial aspect of the upper eyelids was trimmed. Thin strips of preauricular SMAS and fat were also tunneled under the dermis of the frown lines through tiny stab incisions in the skin. Her appearance at 1 year after surgery displays a subtle improvement in all of the treated areas, which, taken together, provided her with a rejuvenated appearance and a refreshed spirit.

Concluding Thoughts

In my thirty-fifth year in practice, I find myself having come full circle in my cheek-lift technique, beginning with a subcutaneous lift, then moving on to various iterations of a SMAS-included lift, before returning to a subcutaneous lift. Over the years, however, I added some things that I believe make the procedure I do now more effective and the results longer lasting: a more generous flap mobilization, a sound method of flap fixation, and an accessory lift to the lower eyelid and temporal zone. This may be an easier, safer, and highly gratifying approach for other plastic surgeons as well.

Clinical Caveats

Inclusion of the SMAS in a compound cheek-lift flap was found to offer no long-term benefit.

Far-reaching subcutaneous undermining is routinely done to release all of the skin and fat-retaining ligaments that might inhibit successful unrolling of the nasolabial fold and the labiomandibular fold and repositioning of sagging malar and jawline soft tissues.

Despite the extensive amount of tissue dissection, a very low incidence of postoperative hematoma is expected because a weak concentration of epinephrine is combined with the local anesthetic, producing relatively weak vasoconstriction of relatively short duration, and because a good deal of the dissection is done with the electrocautery rather than with scissors.

Tension on the flap takes up the slack, while a stable method of flap fixation counteracts the elastic and gravitational forces working against the lift.

The degree of tension must be gauged for safety. A deep dimple or a blanched line in the skin at the site of the fixation suture indicates that less tension must be reapplied.

The locus of flap fixation, high up and far out in the cheek, is ideally situated at the point of convergence of all the vectors needed for a *complete* cheek lift.

A temporal lift and lower eyelid lift are often done in conjunction with the cheek lift to prevent pretemporal and lower eyelid skin bunching and the appearance of a *lateral sweep*.

The best short- and long-term improvement of a prominent jowl is obtained by direct excision of excess or ptotic medial jawline fat.

Small details of skin incision placement are emphasized to avoid postoperative scar visibility and a dislocation of the hairline.

This cheek lift can be done as an independent *short-scar* procedure without a neck lift, or as part of a combined cheek-neck lift.

Annotated Bibliography

Friedland JA. The cutaneous rhytidectomy. In Bernard RW, ed. *Surgical Restoration of the Aging Face*. Boston: Butterworth-Heinemann, 1996.

While most of his colleagues had adopted a SMAS flap face-lift technique, this experienced surgeon stuck with a subcutaneous method, involving extensive undermining, along with a superior and lateral cheek SMAS plication, because of its safety and efficacy. The skin flap was “redraped under tension.”

Gillies H, Millard DR Jr. *The Principles and Art of Plastic Surgery*, vol II. Boston: Little Brown, 1957.

In regard to face-lifting, the senior surgeon noted “the necessity of wide undermining,” saying that it should extend “over the cheek, outer portion of the upper and lower lips and chin,” while observing that “the skin over the malar is often quite adherent and demands a little more care.”

Gosain AK, Amarante MT, Hyde JS, et al. A dynamic analysis of changes in the nasolabial fold using magnetic resonance imaging: implications for facial rejuvenation and facial animation surgery. *Plast Reconstr Surg* 98:622-636, 1996.

This MRI study found that an increased prominence of the nasolabial fold over time was caused by “progressive thickening of the dependent portion of the cheek fat pad and overlying skin, with no appreciable change in the muscle plane” and concluded that “to diminish the nasolabial fold, surgery for facial rejuvenation should be directed to the skin and subcutaneous tissue planes.”

Hamra ST. *The Facelift Letdown*. New York: MDP, 2009.

The developer of the deep plane and composite face lift techniques has abandoned the sub-SMAS dissection in the cheek, saying that “while I originally lifted the SMAS with the cheek fat and eye muscle, I have concluded that it is best left untouched, as moving it toward the ear actually inhibits upward motion of the cheek fat.” His current approach focuses on a strong vertical lift to the tissues of the upper cheek, periorbital area, and lateral orbicularis oculi muscle, which is done through a lower eyelid incision—along with a subcutaneous cheek-neck lift done through a periauricular incision.

Hoefflin SM. The extended supraplatysmal plane face lift. *Plast Reconstr Surg* 102:2513, 1998.

In this letter to the editor, the author says the following: "I do not feel that a platysma aponeurosis or SMAS dissection is necessary and, at times, I think it is contraindicated. Long-term results much too frequently show SMAS banding, overlying 'sweep,' and animation abnormalities. These problematic results, often seen and published, caused me to pursue techniques other than a subplatysma technique. I believe that the platysma aponeurosis (SMAS) has a very important function in not only uniformly supporting, but also finely coordinating, the facial mimetic muscles and normal facial animation. Although many excellent surgeons continue to successfully use a two-level dissection, I do not."

Lambros VS. The superficial musculoaponeurotic system rhytidectomy. In Bernard RW, ed. *Surgical Restoration of the Aging Face*. Boston: Butterworth-Heinemann, 1996.

The author observed that "the results of a SMAS face lift, a skin face lift, or a combination lift may be indistinguishable."

Mayer DM, Swanker WA. Rhytidoplasty. *Plast Reconstr Surg* 6:255, 1950.

This was the very first article on face lift surgery to appear in Plastic and Reconstructive Surgery. The authors stated that "the longevity of the result is directly proportional to the extent of the undermining."

CHAPTER 37

Midface Recontouring

T. RODERICK HESTER, JR.,
J. NICOLAS MCLEAN

Surgical rejuvenation of the aging face has become one of the most frequently performed surgical procedures in the United States. Loss of volume and gravitational descent combine to create an appearance of facial aging that is evident in all facial features. The youthful eyelid's almond-shaped horizontal palpebral fissure, with its slight upward slant from the medial to lateral commissure, changes and elongates with aging, creating a rounder shape with increasing scleral show. As the malar fat pad descends, cheek prominence is lost, and malar bags may occur. The nasolabial fold deepens, and the tear trough deformity may appear. In summary, the vertically short youthful orbit elongates with aging.

Correction of aging changes in the lower lid and midface is essential for producing a balanced, natural-appearing result after surgical facial rejuvenation. Options for achieving these rejuvenative goals include endoscopic procedures through a temporal approach with suspension sutures to reposition midfacial tissue, open face-lift procedures with superficial musculoaponeurotic system (SMAS) plication, and direct repositioning of the malar fat pad.

Our preferred technique for correction of aging in the critical zone encompassing the lower lid and midface is based on three basic principles:

1. Direct vertical elevation and fixation of midfacial descended soft tissue
2. Orbicularis oculi superolateral redraping with suturing to the periosteum of the lateral orbital rim and temporalis fascia
3. Volume replacement and fat repositioning

Our approach to lower lid and midface rejuvenation includes the following:

- A lateral lower lid incision with minimal myotomy to allow for endoscope-assisted subperiosteal dissection
- Release of malar soft tissues
- Orbicularis oculi muscle redraping

Evolution of Technique

The senior author (T.R.H.) has been using the trans-lower lid blepharoplasty, subperiosteal midface dissection for rejuvenation of the lower lid and midface since 1994. Our approach to transorbital midface rejuvenation has been influenced significantly by the work of others. The subperiosteal approach in facial rejuvenation

was first described by Tessier. Psillakis and Ramirez expanded and further described the use of subperiosteal dissection and release of the midface. Hamra emphasized the importance of vertical elongation of the aged orbit, and both Ramirez and Hamra emphasized the importance of vertical elevation of midfacial soft tissue as more appropriate for correction of midfacial aging. McCord, Codner, and Jelks et al have significantly influenced our own technique for rejuvenation of the lower lid component while minimizing the risk of complications.

The senior author's experience with transorbital midfacial rejuvenation has been previously documented. Since the original description more than 16 years ago, it has evolved from an "open" lower lid approach to an endoscopically assisted approach that avoids dissection and trauma in the plane between the orbicularis oculi and orbital septum, reducing the chance for postoperative lower lid malposition.

Indications and Contraindications

Any patient with aging of the lower lid and midface is a candidate for this procedure. In our experience, the direct vertical elevation of the midface and redraping of the orbicularis that occur with this technique result in a more pleasing and natural appearance than could be obtained with traditional lateral-vector techniques. The senior author now uses this procedure in all face lifts, thereby eliminating the need for extensive lateral to central deep-plane or sub-SMAS dissection. We have found, however, that patients with more severe degrees of facial volume loss, especially when this is accompanied by malar bony retrusion, will have less than ideal outcomes unless the volume deficiency is addressed. In these patients, autologous fat grafting and/or appropriate facial implants will significantly improve results.

The midface lift is not used to improve the aging changes inferior to the oral commissure and along the inferior mandibular border. In this situation, a traditional face lift with a more lateral-vector preauricular and postauricular approach is used to better correct aging in these areas, including the lower neck.

Pertinent Anatomy

Familiarity with the anatomy of the face, specifically the lower lid and midface, is essential for a successful outcome with this procedure. The following anatomic principles apply.

In this difficult zone of the face, it is important to understand the anatomic changes associated with aging and have a clear vision of what needs to be accomplished for correction. Surgically, the midfacial area moves as a unit, behaving as a composite structure because of the firm attachments of the suborbicularis oculi fat and malar fat to the orbicularis muscle. The orbicularis–facial fat complex is invested with the SMAS, which emanates from bony periosteal attachments at the inferior orbital rim and zygoma. It penetrates through the orbicularis fibers outward and extending to the malar subcutaneous fat, where it permeates and divides the anterior fat. This system of cheek attachments allows full cheek movement and repositioning by upward tension and supraplacement of the orbicularis arc of muscle.

The malar fat pad is superficial to the SMAS. The deep suborbicularis oculi fat (SOOF) lies beneath the SMAS and orbicularis oculi. This anatomic relationship allows the SMAS, orbicularis, and periosteum to be used as a “musculoligamentous carrier” to reposition midfacial fat superiorly, rather than depending on sutures in the structurally weakest component of cheek soft tissue—the fat.

As aging occurs, the more lax lower lid skin, muscle, and fat descend over the relatively fixed orbitomalar ligament, creating a malar bag. Likewise, with descent of cheek soft tissue over the relatively fixed nasolabial retaining ligaments, the fold may deepen.

A major component of lower lid and midfacial aging is laxity of the orbicularis muscle. The orbicularis derives innervation from the zygomatic branch of the facial nerve laterally and the buccal branch medially. It appears from our studies that the pretarsal orbicularis, the critical segment responsible for the blink reflex, derives its innervation nasally via the buccal branch. The remaining body of the orbicularis is responsible for tight closure of the lids and serves to protect the globe from trauma.

The lower lid is highly intolerant of misguided surgical trauma. Traditionally, lower lid rejuvenation is performed using open preseptal dissection. In our technique, the septum remains attached to the orbicularis when the muscle is redraped superolaterally, eliminating the need for excision or other manipulation of the septum and decreasing the possibility of traumatically induced scarring and lid retraction.

Because dissection and release of midfacial soft tissue are done in the subperiosteal plane with the use an endoscope, anatomic concerns related to sensory or motor nerve damage are minimized. All motor branches of the facial nerve are above the plane of dissection and “out of harm’s way,” and there is no denervation of the orbicularis muscle.

The infraorbital nerve (V2; the maxillary division of the trigeminal nerve) is the most important sensory nerve encountered during subperiosteal cheek dissection. It emerges through a foramen in the malar bone approximately 2 cm below the infraorbital rim and 2 cm lateral to the nasomaxillary fissure. This nerve provides sensation to the body of the cheek, lateral nasal skin, and lateral upper lid. Surgical trauma can result in significant, prolonged paresthesia over these areas.

The zygomaticofacial nerve emerges through a small foramen in the zygoma approximately 4 cm below the lateral canthus and provides additional sensation to the lateral malar skin and cheek. This nerve is usually small and is often divided during the dissection. In our experience, division of the zygomaticofacial nerve is of little consequence, occasionally resulting in a minor temporary paresthesia (see Chapter 40 for a detailed discussion of facial anatomy).

Preoperative Assessment

Preoperative assessment should include a detailed history of any medical problems, but focused to general eye health, dry eyes, personal or family history of glaucoma, LASIK procedures, and a physical evaluation of lid tone. As a safety measure, we wait at least 6 months before performing any eyelid procedure in a patient who has recently had LASIK surgery. We have a low threshold for requesting an ophthalmology evaluation when there is any question.

As is true for all areas of the face, the cause of periorbital aging is multifactorial and necessitates a comprehensive approach if correction is to be optimal. A full evaluation of the face is performed, including the entire periorbital area and the lower face. Particular attention is paid to the lower lid, the lid-cheek junction, and the midface. Aging of the lower lid and midface is characterized by both descent and, in patients who are not obese, some degree of soft tissue deflation. Such changes are looked for and noted.

Important anatomic components of lower lid and midface aging include the following:

- Laxity and descent of the orbicularis muscle
- Laxity of the orbital septum and pseudoherniation of the orbital fat
- Eyelid tone and laxity
- Descent of the lid-cheek junction
- Horizontal laxity of the tarsal plate component of the lower lid
- Descent of the cheek fat pad with laxity of the orbitomalar ligament
- Laxity of the zygomaticus muscles and other elevators of the upper lip
- Loss of soft tissues volume
- Bone deficiency
- In some cases, some degree of deepening of the nasolabial fold

Orbital morphology was determined before surgery by using the Hertel exophthalmometer. This instrument measures the distance in millimeters from the anterior-most point of the lateral orbital rim and the anterior border of the globe.

Loss of soft tissue volume exaggerates the effects of soft tissue descent. In fact, some surgeons think that volume loss is the most important component of facial aging. There is certainly thinning of the tear trough, with deepening of the nasojugal groove. As the midface descends and deflates, there is concomitant lengthening and thinning of the upper lip and subtle descent of the lateral oral commissure. Finally, actinic skin changes with accompanying collagen degradation result in surface aging, with skin thinning and increasing numbers of both static and expression-induced wrinkles.

Patient Education

Patients should be informed of potential morbidity after lower lid rejuvenation combined with midfacial rejuvenation. Potential morbidities include the following:

Swelling: Periorbital swelling is most significant in the first 3 to 4 days after surgery. Head elevation, ice, and occasionally a diuretic are the most effective treatments. More chronic, lesser degrees of swelling in the lateral orbital area can require 3 to 5 weeks to totally resolve. Total surgical maturation can require several months.

Incisions: The lateral extensions of the upper and lower lid incisions will be obvious for the first 3 to 4 weeks. These gradually fade into lateral orbital creases, but in a few patients these may require revision (laser, dermabrasion, or surgical).

Nerve injury: Sensory paresthesia related to surgical manipulation of the infraorbital nerve occurs in a few patients and is usually minimal and short lived. There is near-zero chance of motor nerve injury when the procedure is done properly using the subperiosteal plane of dissection.

Lower lid malposition: When the technique is performed properly, the chance that significant ectropion will occur is extremely low. However, older patients with horizontal lower lid laxity of 6 mm or greater with an exophthalmometer measurement of 18 mm or less should have appropriate horizontal lid shortening and canthal support to prevent lesser degrees of lower lid malposition.

Operative Technique

Markings and Incisions

The proposed incision in the upper eyelid is marked according to the patient's morphologic and aging changes. A subciliary lower lid incision is marked on the lower eyelid with a short lateral extension within the preexisting skin line (if present).

Patient Positioning and Anesthesia

The operation is performed with the patient supine and the head slightly elevated. The corneas are protected with either ointment or plastic protectors, according to individual preferences. We usually perform this operation with the patient under general anesthesia, because it is combined with other aesthetic procedures.

Upper Lid Blepharoplasty: Exposure of the Lateral Orbital Rim and Temporal Fascia

If required, an upper blepharoplasty using an open-sky technique is performed to remove skin and muscle of the upper eyelid and to expose the lateral orbital rim and temporal fascia. Laterally, the orbital rim is identified; here it is very important to leave the periosteum intact, because it will serve as the point of midface fixation. Laterally to the orbital rim, the temporal fascia is exposed sufficiently to allow eventual midface fixation. Selectively, if needed, conservative fat excision from the upper eyelid is performed.

Midface Dissection

A subciliary lower lid skin-only incision is made extending 10 to 12 mm lateral to the lateral canthus. This incision will be parallel and located approximately 5 to 7 mm inferior to the lateral extension of the upper blepharoplasty incision. Through the lateral extension of the incision, a small myotomy large enough to pass an endoscope is performed in the orbicularis muscle to allow a preperiosteal dissection of the inferolateral orbital rim, connecting superiorly with the dissection previously performed through the upper lid. The pretarsal orbicularis is not divided.

Through the lateral myotomy on the orbicularis oculi, subperiosteal dissection and release of midfacial soft tissue are accomplished with a periosteal elevator under direct vision with endoscopic assistance. This dissection totally spares the pretarsal and preseptal portions of the orbicularis oculi muscle as well as the entire orbital septum, significantly reducing surgical trauma within the middle lamella of the lower lid. Dissection continues medially along the orbital rim, above the infraorbital nerve to the nasomaxillary suture line, and below the infraorbital nerve; the dissection also extends to the nasolabial fold medially, the lower edge of the malar bone inferiorly, and to the junction of the anterior and medial third of the zygomatic arch posteriorly. The extent of this dissection results in release of the soft tissues of the cheek, allowing subsequent elevation and fixation. The dissection includes a release of the tendinous origins of the levator labii superioris and zygomaticus major and minor, the suborbicularis fat pad, the lower third of the orbicularis oculi muscle, the cheek fat pad, and finally, overlying skin, which can be vertically elevated as a unit. Because the dissection is subperiosteal, branches of the seventh nerve to the involved muscles are not at significant risk.

Elevation and Fixation

A skin flap is elevated along the lateral third of the subciliary incision, exposing the underlying full-thickness cheek flap to allow fixation. A suture is placed through the already elevated cheek flap and then passed under the skin bridge between the upper and lower lid incisions. Initial fixation is performed to the temporal fascia above the arch and just behind the lateral orbital rim. A very important second suture brings together the medial edge of the elevated flap to the periosteum on the inner surface of the lateral orbital rim. This step provides additional fixation for strength and pulls the lid against the globe.

As the orbicularis muscle flap is redraped and tightened, the septum is also tightened, resulting in reduction of herniated postseptal fat, eliminating the need for fat excision in most cases. Retention of this lateral segment allows anatomic repair of the lower lid and provides a “passive tightening” of the lateral canthal tendon and

eliminates the necessity canthopexy. In an occasional patient, the nasal fat pad may be particularly prominent and may not be adequately reduced with septal tightening alone. In this rare situation, reduction of the offending pad is performed several months postoperatively using a simple transconjunctival approach.

Excision of Lower Lid Skin

Lower lid skin is excised conservatively. Uncorrected lower lid laxity can lead to postoperative malposition and lid retraction. In both primary and secondary patients, no matter how secure the midface fixation and canthal support, a deficiency of skin in the lower lid will invariably result in postoperative lower lid malposition.

A guide for skin excision is as follows:

- From the medial canthus to the pupil, 0 to 1 mm
- From the pupil to the lateral canthus, 1 to 3 mm
- Lateral to the lateral canthus, 4 to 6 mm

Overresection of lower lid skin will cause lower lid malposition, and overresection on the nasal side of the pupil is the most problematic.

In all patients, orbital morphology is evaluated preoperatively; lower lid laxity is assessed intraoperatively and corrected if indicated. Lower lid laxity can be assessed using the snap-back test or the more accurate distraction test. The upper border of the lower lid is grasped as it crosses the base of the limbus. If the lower lid can be pulled 6 mm or more away from the globe, significant laxity is present and a horizontal lid shortening should be performed.

When indicated, a 2 to 4 mm full-thickness wedge of the ciliary margin and the tarsal plate is excised.

Volume Replacement

Freshly aspirated fat is harvested and 1 to 2 cc is injected into the medial tear trough through a 21-gauge blunt needle. If indicated, additional amounts of fat (5 to 8 cc) are injected into deficient zones of the cheek and lower face.

Early on we began using autologous fat injection to better cover the inferior orbital rim and add indicated volume to the tear trough and nasojugal groove.

Conversely, we found it helpful in patients with deep nasolabial folds to reduce volume in the medial edge of the fold by suctioning with a small 1 or 2 mm cannula.

Brow Repositioning and Neck Lifting as a Component of Midface Rejuvenation

Lower lid and midface rejuvenation is usually done as an important component of comprehensive facial rejuvenation. In essentially all cases, some degree of brow repositioning is necessary. Our preferred technique is an endoscopically assisted subperiosteal approach that includes resection of the corrugator and procerus muscles. If the central brow is not an issue, a limited lateral approach is used. The purpose of the brow manipulation is to correct brow ptosis when present, and, just as important, to smooth and redrape lateral orbital soft tissue excess that occurs with the powerful vertical vector cheek lift. (See Chapter 24 for detailed information on endoscopic brow lift.)

A lower face and neck lift is also performed in patients with significant aging at and below the oral commissure and in the neck. Preauricular and postauricular incisions are used. Sufficient subcutaneous dissection is done to allow lateral plication of the lower SMAS and platysma. As indicated, treatment of the midline of the neck is performed through a submental incision.

Rejuvenation of the midface as we have described eliminates the need for extensive lateral to medial sub-SMAS dissection in the cheek and lower face.

Because the lateral brow is elevated with endoscopic assistance, it is not necessary to extend the preauricular incision into the temporal scalp. Thus elevation of the sideburns or a potentially visible scar in the hair line is avoided.

The vectors used for comprehensive facial rejuvenation are depicted.

Skin Resurfacing

When indicated, skin rejuvenation with an erbium laser or a peel is performed at this stage. If concomitant aesthetic facial procedures are planned, the peel or laser should be the final step after completion of those procedures. Concomitant skin rejuvenation with this procedure is safe, because the dissection of the midface is done in the subperiosteal plane, and the blood supply to the skin is not significantly affected. When the procedure is combined with a face and neck lift, there is limited subcutaneous dissection of preauricular skin, and resurfacing should be superficial to the affected zones.

Postoperative Care

The postoperative course for patients undergoing this technique is comparable to other comprehensive rejuvenation operations. Periorbital swelling can be troubling early, and care must be exercised to protect the globe with drops and ointment. By 2 weeks postoperatively, all sutures and fixation devices are removed. By the third to fourth week, most patients can manage with appropriate cosmetic coverage techniques; 2 to 3 months is required for more complete healing, and in general, revisions are not done for 6 months.

Problems and Complications

The senior author has more than 20 years of experience with the transorbital approach to lower lid and midface rejuvenation in more than 1500 patients. As indicated earlier, the original technique was through an “open” lower lid, incorporating a subciliary incision with a traditional skin-muscle flap dissected to the orbital rim. An overview of this experience was published in 2000. Although overall results were excellent, a small but troubling number of patients had postoperative lower lid malposition, possibly related to the extensive lower lid dissection required. Some patients developed minor degrees of webbing or blunting of the lateral canthal angle secondary to canthoplasty. To minimize these problems, two important modifications of the technique were incorporated in 1999. Open dissection of a skin-muscle flap in the lower lid was abandoned in favor of a “closed” endoscopically assisted approach that avoids dissection in the body of the lower lid. This modification of technique significantly decreased the rate of postoperative lower lid malposition. In addition, canthoplasty involving a transcanthal incision has been eliminated. In 2005 new steps were added to further improve the results, virtually eliminating the incidence of severe lower lid malposition. These new steps included the intraoperative correction of significant horizontal lower lid laxity and decreasing operative septal trauma.

The importance of “deflation” as a significant component of facial aging, in many cases, has stimulated us to be more aggressive with volume replacement when indicated. The use of autologous fat grafting is certainly an attractive option in these cases. However, not all plastic surgeons are enthused about the success rates for fat grafting. In our experience, fat grafting has been useful, but success appears to be very technique dependent. It is important that aspiration be as atraumatic as possible and that injections be done with small-gauge, blunt needles, with small amounts injected in multiple passes. We have also used solid silicone cheek and orbital rim implants, especially in patients with severe degrees of maxillary retrusion.

Outcomes

The very low incidence of this troublesome morbidity is probably related to the decreased trauma to the lid and lateral canthus inherent in the technique. We found that in most cases the tightening of the pretarsal orbicularis muscle that occurs with these modifications provided excellent lower lid support and eliminated the need for a formal canthoplasty. Because the muscle was not dissected off the septum, orbicularis redraping passively tightened the septum, thus reducing postseptal fat herniation without the necessity of direct septal manipulation.

A 2009 article by the senior author highlighted very important steps to decrease complications in lower lid and midface rejuvenation, with the finding that patients with horizontal lid laxity of 6 mm or greater with an exophthalmometer measurement of 18 mm or less were at increased risk of lower lid malposition. When significant horizontal lower lid laxity is present, a lateral lower lid wedge excision is used as described earlier. This maneuver spares the angle and markedly decreases the incidence of healing deformity of the lateral canthal angle. Our experience suggested that patients with enophthalmic orbits combined with horizontal lower lid laxity are also at increased risk.

It should be emphasized that the passive septal tightening that occurs is very effective in correcting postseptal fat prolapse without the trauma inherent in open lower lid procedures.

Results

This 54-year-old woman is shown before and 1 year after closed endoscopically assisted midface lift and brow lift with appropriate skin excision in the upper and lower lids. She also had fat injection along the orbital rim and erbium laser skin resurfacing for acne scarring. The split-view clearly confirms the elevation of the lid-cheek junction, softening of the nasolabial fold, and decreased corrugator and transverse forehead wrinkles without overskeletonization of the upper and lower lids.

Desiring midface rejuvenation and a more uplifted appearance, this 57-year-old woman underwent an endoscopically assisted midface and brow lift, neck lift, and a TCA peel. She was very pleased with the results, which provided elevation of the lid-cheek junction and oral commissure and rejuvenation of her jowls and neck. She is shown 18 months after treatment. The oblique views and split-view dramatically demonstrate the midface elevation that has been achieved.

This woman is shown before and 1 year after a closed endoscopically assisted mid-face lift and brow lift with appropriate skin excision in the upper and lower lids.

Clinical Caveats

Trauma can be limited by eliminating preseptal dissection in the body of the lower lid and endoscopically assisted subperiosteal dissection of midfacial soft tissue.

Elevation and fixation of the midface should be vertical rather than lateral.

The technique involves vigorous vertical elevation and redraping of the orbicularis oculi.

Patients with horizontal lid laxity of 6 mm or greater with an exophthalmometer measurement of 18 mm or less are at increased risk of lower lid malposition.

Horizontal lower lid laxity is corrected intraoperatively when present.

Volume should be replaced when indicated.

Skin rejuvenation should be performed when indicated.
